LIST OF ILLUSTRATIONS

PAGE
Ambulance, Light Trailer (J. L. Moir) .. 160
Aneurysm Needle Technique, Instruments for (H. Dodd) .. 100
Artery, Innominate, Ligature of, for Right Subclavian Aneurysm (Sir W. I. de C. Wheeler) .. 422
Asphyxia in Haemophiliac (C. L. Endicott and others) .. 34
Bagassosis, an Industrial Lung Disease (L. I. M. Castleden and J. L Hamilton-Paterson) .. 478
Bed and Cot Tents (C. Paget Lapage) .. 726
Birks, Francis Joseph .. 56
Bladder, Urinary, a Pencil in the (Eric W Bintcliffe) .. 543
Bronchography, Posturing in (F. D. Hart) .. 8
Cancer of Lower End of Common Bile Duct and Adjacent Pancreas, Radical Surgery of (G. Gordon-Taylor) .. 120
Carditis, Unsuspected Rheumatic, Sudden Death (J. T. Quinlan) .. 695
Carotinaemia (S. Almond and R F. L. Logan) .. 239
Chip Fractures of the Os Triquetrum (Carpal Cuneiform) (T. J. Fairbank) 310
Chronic Leg Ulcer in Myelogenous Reticulosis (Cyril John Polson) .. 481
Circulatory Overloading following Rapid Intravenous Injections (E. P. Sharpey-Schafer and John Wallace) .. 304
Circumcorneal Injection in Riboflavin Deficiency (H. Scarborough) .. 601
Crush Syndrome, Prophylactic Treatment of (D. H. Patey and J. D. Robertson) .. 212
Crushing Injury (E G. L. Bywaters) .. 643
Dislocation, Old-standing, of the Knee-joint, Reduction of (F. P. Fitzgerald) 542
Diverticulum of Jejunum (F. E. C. Devegney and H. Bailey) .. 98
Fatal Phosphorus Poisoning from an Explosive Bullet (A. J. Blaxland) . 664
Fawcett, Edward .. 412
Forearm, Mangled: Treatment in Skeleton Splint with Fixed Skeletal Traction (David Brown) .. 425
Fracture Redressor, Simple (G. A. G. Mitchell) .. 697
Gas-gangrene Infection of Foetus (F. H. Kemp and J A. Stallworthy) 94
Gastrectomy, Total, Long Survival after (Cecil A Joll and D. I. Adler) .. 632
Health of the Doctor (A. Hope Gosse) .. 567
Hepatitis, Comments on an Epidemic of (P Evans) .. 447
Hernia, Femoral, Needle for Repairing (J. W Stretton) .. 131
Hyperostosis Frontalis Interna (C. T. Andrews) .. 186
Hyperostosis Frontalis Interna (H Ucko) .. 408
Intramural Intestinal Haemorrhage (D. Cromie) ..
Louse-borne Typhus Fever (Sir J. W. D. Megaw) ..
Malaria in England, Diagnosis and Treatment of (W. Yorke) ..
Migraine, the Pain Pathways in (G. F. Rowbotham) ..
Muscle Recovery and Range of Joint Movement: Apparatus to Measure (G. A. Pollock and G. Brooks) ..
Mustard-gas Burns (J. Grant and T. F. Ritchie) ..
Night Vision in the Army (B. W. Rycroft) ..
Nutritional Iron Deficiency Anaemia in Wartime (L. S. P. Davidson and others) ..
Otitis Media, Chronic, Morbid Anatomy of (W O. Lodge) ..
Pneumococcal Meningitis successfully treated with Sulphapyridine (E. Meurig Williams and Elliot Philipp) ..
"Railed" Splint (G. A. Pollock and George Brooks) ..
Reception of Casualties in an E.M.S Hospital (Stanley J. Firth and Harold Park) ..
Rectal Administration of Fluid (D. C. Corry) ..
Respiratory Rhythm in Malignant Hypertension (H. O. Gunewardene) ..
Sedimentation Rate and the Sedimentin Index (B. L. della Vida) ..
Service Ether Vapour Apparatus (J. C. H Brown and W. E. Counihan) ..
Silicosis in a Chert-miner (C. W. Evans) ..
Sphincter Mechanism of Lower End of Bile Duct (G. Gordon-Taylor) ..
Splint for First-aid Treatment of Fractures of the Leg (A. P. Phillips) ..
Stirrup, Director (E. T. Bailey) ..
Stomatitis, Ulcerative Membranous (T. C. Henry) ..
Surgical Amputations and the Fitting of Artificial Limbs (A. W. J. Craft)
Syringe for Continuous Intravenous Anaesthesia (S. C. Lewsen) ..
Thomas Splint, a Modification of (M. P. Laufer) ..
Trench Fever (Sir Arthur Hurst) ..
Twins, Conjoined (E. Ridehalgh) ..
Varicose Veins in Soldiers, Treatment of (E. L. Farquharson) ..
Venous Pressure during Venesection and Blood Transfusion (J. F. Loutit and others) ..
Walker, Sir Norman ..
War Surgery of the Eye: Removal of Magnetic Intra-ocular Foreign Bodies by the Posterior Route (H. B. Stallard) ..

~~636~~ P. 25508

INDEX TO VOLUME II FOR 1942

READERS in search of a particular subject will find it useful to bear in mind that the references are in several cases distributed under two or more separate headings—for example, Brain and Cerebral; Heart and Cardiac; Liver and Hepatic, Renal and Kidney; Cancer and Carcinoma; Child and Infant; Goitre and Thyroid. Subjects dealt with under various main headings in the JOURNAL have been set out in alphabetical order under their respective headings—for example, "Annotations," "Correspondence," "Leading Articles," "Obituary," "Reviews," etc. Original Articles are indicated by the letter (O).

A

Abdomen, non-penetrating injuries of (Th. Schrire), 127 (O)—Correspondence, 300, 356
Abscess, amoebic liver, 199
Abyssinia: Relapsing fever in Addis Ababa (P. Robinson), 216—Aid for women and children of, 534
Academy, Royal, of Medicine in Ireland: Rupture of the uterus, 735
—— of Medicine, New York: *March of Medicine*, 130
Accidents: Unusual, 118—Under Factories Act, 234—Personal factor in, 343—And sickness in miners, 711
Acne vulgaris, endocrine factors in, 75
Actinomycin A, isolation of, 606
ADAIR, A.: Scientific journals for enemy prisoners of war, 469
ADAMS, A. Wilfrid. "Positive health," 138
—— E. W.: The teaching of first aid, 707
Adder bite, 118, 178—Case of (D. Stanley-Jones and Charles E. S. Harris), 395—(Paul Szekely), 608
ADLER, D. I. (and Cecil A. JOLL): Long survival after total gastrectomy, 632 (O)
Adrenaline bronchoconstriction, 82
Adrenals in anoxia and in shock, 193—Haemorrhagic suprarenal infarction, syndrome of (Doris V and Kenneth D. Keele), 687 (O)
Advancement of Science, Vol. II, No. 7, 755
Aetiology of phlyctenular ophthalmia, 373
Africa: Native medicine, review of book on, 42
After-treatment, review of book on, 99
AINSLIE, John Z. (and E. Cunningham DAX): Blood pressures after injection of K salts, 768
Air disinfection: By light, 18—New method of, 431—Correspondence, 557
Air-raid casualties, colour film of, 654
AIREY, Geoffrey G.: The Planning Commission's Report, 52, 265—Medical planning now, 561—Device for making fomentations, 626
Alcohol in T.A.B.C. vaccine (J. C. Cruickshank and others), 182 (O)
Alcoholism, acute, biochemistry of, review of book on, 368
Aliens: Dentists, 146
Alimentary tract, foreign bodies in (G. O. Chambers) (O), 362—Correspondence, 467
Alkaline haematin method, estimation of haemoglobin by (J. W. Clegg and E. J. King), 329 (O)
ALLEN, Clifford (and C CARLYLE-GALL): Depression-hyposexual–alopecia syndrome, 67 (O), correspondence on, 174, 263
—— F. M. B.: Future of paediatrics, 226
—— W. J. R.. Dehydration of foods, 254
AMOND, S. (and R. F. L. LOGAN): Carotinaemia, 239 (O); correspondence, 380
Alopecia, depression, and lowered sexuality (C. Allen and C. Carlyle-Gall), 67 (O)—Correspondence, 174, 263
ALPER, Benedict S. (and W. HEALY). *Criminal Youth and Borstal System*, 12
Ambulance: National service, 103—Light trailer, 160, 296, 566—For Home Guard, 328

AMERICA:
  Chastek paralysis in silver foxes, 105
  Drug Addiction, report of Committee on, 665
  Medical Association, review of book on, 637
  Surgical practice of the Lahey Clinic, Boston, Mass., 726

America, Latin, study of nutrition in (Pedro Alberto Escudero), 698
Amputation: Discussion on, 51—Syme's, 53—"Fibro-psychosis" of stump, 231—And artificial limbs (book review), 313—Surgical and fitting of artificial limbs (A. W. J. Craft), 698 (O)
Anaemia: In x-ray workers, 137, 291, 377—In young adults—dietetic? 467, 566, 596
—— megaloblastic, of pregnancy and puerperium (L. S. P. Davidson and others), 31 (O)—Correspondence, 198, 256, 350
—— nutritional, 682—In women and children, 586
—— —— iron deficiency in wartime (L. S. P. Davidson and others), Part I: Haemoglobin levels of 831 infants and children, 505 (O), 587
—— pernicious, 176, 291
Anaesthesia, single-handed, and operation, 295, 407—Syringes for continuous intravenous 428—Convulsions under trilene, 607—For tonsillectomy, 649
Anaesthetic convulsions, 296, 679
—— death, 411—Epiglottis in, 344—In surgery, 170, 263, 351
—— trichlorethylene as general, 170, 258, 496
Anaesthetics. Complacency in, 23, 54, 110, 169, 264—Leading article on, 73; correspondence, 300
Analeptics, hypnotics, and mental disease, 45
Analgesics given by midwives, 86
Analytical chemists and E.M.S. laboratories, 84
Anatomy: Review of series of pictorial aids to, 578
—— of cutaneous sensibility (leading article), 342
—— teaching of, 138
ANDERSON, Robert: Lister technique for emergency surgery, 406—Prevention of small-pox, 617
—— William Kirkpatrick, obituary notice of, 144
ANDREWES, C. H.: Influenza epidemics: some conundrums, 556
ANDREWS, C. T.: Hyperostosis frontalis interna, 185 (O)—Correspondence on, 261, 292, 353, 408, 621
Aneurysm: Instruments for needle technique, 100
—— Right subclavian, ligature of innominate artery for (Sir W. I. de C. Wheeler) 422 (O)
ANGELMAN, Joseph: Bleeding tooth sockets, 504
Anglo-Iranian Pharmaceutical Company, Limited, formation and registration, 772
ANGYAL, Andras: *Foundations for a Science of Personality*, 247
Animals: And plague, 229—Haemophilia in, 250
Annals of Medical History, suspension of publication, 773
ANNAN, W. Gillies: Control of venereal disease, 617

Annotations:
  Accidents, personal factor in, 343
  Acne vulgaris, endocrine factors in, 75
  Adrenals in anoxia and in shock, 193
  Aetiology of phlyctenular ophthalmia, 373
  Air disinfection: By light, 18—New method, 431
  Ambulance service, national, 103
  Antibody reaction, photographing, 104
  Antisepsis, intestinal, 162
  Ascorbic acid, synthesis of, by animal tissues, 583
  Asphyxia, resuscitation from, 614
  Azotaemia, extrarenal, 730
  Bed-bug, 134
  Blind in wartime, work for, 520
  Blood: Drying of plasma and serum, 18—Flow to limb muscles, 164—Brain barrier, 703
  Blood–brain barrier, 703
  Bread, biological values of, 76
  Cancer: An organized treatment of, 46—Diethylstilboestrol for prostatic, 641
  Cataract operation, 519
  Chemotherapy, rationalizing, 223
  Child Health, chair of, at Newcastle, 317
  Clean city: pamphlet, 104
  Clinical Journal, jubilee of, 642
  Colon, action of drugs on, 431
  Conjunctivitis, inclusion, 224
  Cripple, mind of, 135
  Curare, therapeutic uses of, 224
  Death certification, confidential, 164
  Delinquency, juvenile, to-day, 582
  Diarrhoea and vomiting, 102
  Dicoumarin, 46
  Diethylstilboestrol for prostatic cancer, 641
  Doctors as politicians and strategists, 16
  Documentary reproduction, 103
  Drugs, action of, on the colon, 431
  Egg-white injury in man, 548
  Endocarditis, subacute bacterial, 669
  Enteritis, regional, prognosis in, 398
  Epidemiologist, a great (*Papers of Wade Hampton Frost*), 399
  Epidemiology of the countryside, 459
  Epiglottis in anaesthetic deaths, 343
  Eye, caustic burns of the, 487
  Fits, faked, and absent records, 702
  Flies: How they take off, 670
  Fructosuria, essential, 373
  Gastro-intestinal concretions 757
  Glucose, rectal, 486
  Gonorrhoea, good and bad chemotherapy for, 549
  Gramicidin, 17
  Haemophilia in animals, 251

Annotations (*continued*):
  Haemorrhage from gastritis, 487
  Health, public, review of, 488
  Heart: Failure, tourniquet for, 702—Conducting system of, 729
  Heparin in practice, 459
  Hereditary factor in cardiovascular disease, 135
  Hospital contributory and provident schemes, 758
  Hypertension in unilateral renal disease, 75
  Hypnotics, analeptics, and mental disease, 45
  Hypoglycaemia from protamine insulin, 250
  Indexes, half-yearly, 194
  Infancy, loneliness in, 345
  Influenza, immunization against, 547
  Information or propaganda? 317
  Laterality dominance in Shakespeare, 432
  Lekarz Wojskowy, 103
  London's bill of health for 1941, 613
  Maisky, Madame, presentation to, 730
  Malaria in Britain, 75—Treatment of, 286
  Man and his environment, 614
  Maternal pulmonary embolism, 372
  Medical films, British, wanted, 759
  Mental disease, maleness, femaleness, and, 432
  Microglia and nerves in posterior pituitary, 488
  Midwives, shortage of practising, 345
  Mononucleosis, infectious, 669
  Myasthenia gravis, drugs for, 730
  Nephritis, acute haemorrhagic, prognosis of, in childhood, 163
  Nicholls, A. G., and the *C.M.A.J.*, 316
  Night vision, 583
  Nuffield, Lord, awarded Hon. Medal of R.C.S., 194
  Oxygen poisoning, 316
  Papworth's progress, 317
  Phosphorus diet, low, and experimental rickets, 399
  Pituitary, posterior, pure protein from, 17
  Premarital Examination Laws in U S.A., 285
  Pulse, charting the, 728
  Quinine, new sources of, 759
  Rat-bite fever, 519
  Rheumatic fever, prophylaxis of, 728
  School meals: What the child thinks, 194
  Seasonal influences, 284
  Serum, pharmacological properties of, 372
  Sex (maleness and femaleness) and mental disease, 432—Rhythm of female cycle, 701
  Shakespeare, laterality dominance in, 432
  Simmonds's disease, 163
  Skin, facial, electrical resistance of, 642
  Statistics, fertility, 76
  Sterilization of dry powders, 134
  Sterols, their structure and action, 459
  Sulphanilamide in acute nephritis, 194
  Sulphathiazole, epileptogenic property of, 548
  Sulphonamides and metabolism of bacteria, 134
  Surgery in Libya, 16
  Tannic acid, burns, and the liver, 703
  Toxicity of mercurial diuretics, 520
  Transfusion of bovine plasma and serum, 251
  Tuberculosis. In old people, 286—Chemotherapy for, 759
  Ulcer, gastric secretion and, 549
  U S.S.R., food problems in, 670
  Vitamin A, clinical import of recent work on, 613
  —— B deficiency: And Wernicke syndrome, 249—And the nervous system, 285
  —— C and resistance to infection, 518
  —— D, too much? 582
  Wernicke syndrome and vitamin B deficiency, 249
  Whooping-cough. High flying for whoopers, 758
  Xanthoma tuberosum a rare cause of sudden death in early life, 641

Anoxia. Adrenals in, 193—And crush injuries, 495, 588
Antenatal and Postnatal Care (F. J. Browne), 4th ed., 341
Antibody reaction, photographing, 104
Anti-pernicious-anaemia factor (leading article), 668
Antisepsis, intestinal, 162
Antiseptic technique, 291, 349, 377, 406, 438, 466
Anuria, duration of, 60
Anxiety states, treatment of, in panel practice, 774
Aortic regurgitation and mitral stenosis, 619
Aphasia in backward children, review of book on, 190
Apple, pear, and carrot treacle, 356

APPLETON, Arthur B.: Teaching of anatomy, 138
—— Sir Edward: Dehydration of foods, 254
APTEKAR, Herbert H.: *Basic Concepts in Social Case Work*, 72
Argentina: Buenos Aires National Academy of Medicine: 1941 Prize, 235
Ariboflavinosis, three cases of: Circumcorneal injection as a sign of riboflavin deficiency in man (Harold Scarborough), 601 (O)
Armstrong, Major Douglas James Stirling: Death on active service, 501
—— Donald B.: Does health education help? 14
Army: Discharge, 416—Acting rank in, 682
Arrhythmia, cardiac, trilene and, 296
Artery, innominate, ligature of for right subclavian aneurysm (Sir W. I. de C. Wheeler), 422 (O)
Arthritis, bequest for furtherance of work on, 444
ARTHUR, John W.: "Female circumcision" among the Kikuyu, 498
Artificial limbs, surgical amputations and the fitting of (A. W. J. Craft), 389 (O)
Artificial respiration in phosgene poisoning, 148, 208
Ascorbic acid, synthesis of, by animal tissues, 583
Ashley, Surg. Lieut. John Wenlock, obituary notice of, 27
ASHMAN, Richard (and Edgar HULL): *Essentials of Electrocardiography*, 456
Asphyxia: Following dental extraction in haemophiliac (C. L. Endicott and others), 34 (O)—Correspondence, 140—Atypical deaths (N. Patterson), 188 (O)—Correspondence, 263, 323—Resuscitation from, 614
Aspiration, symptoms of distress following (H. P. Fernandez), [illegible]99
Aspirin for asthma, 356, 415, 472, 503, 566, 596
ASSINDER, E. W.: Control of venereal disease, 740
Association, American Medical, cancellation of 94th session, 759
—— Anaesthetists, of Great Britain and Ireland, annual general meeting, 736
—— British Empire Leprosy Relief. Annual meeting, 137
—— British Medical: Bournemouth Division, Salvaged experiences, 195—Chairman, Acting, appointed, 614
—— British Orthopaedic: Delayed union of fractures, 50—Amputations, 51—Joint meeting, 60—Symposium on rehabilitation, 493
—— British Paediatric: Paediatrics in medical planning, 226
—— Hospital Almoners: Conference on Almoners' work, 743
—— Incorporated, of Hospital Administrators, 121
—— Industrial Medical Officers: Posture in industry, 108—Mass miniature radiotherapy, 735
—— National, for Prevention of Tuberculosis: resolution of Council, 684
—— Public Dental Service, 299
Asthma: Aspirin for, 356, 415, 472, 503, 566, 596—Bronchoscopic investigation in children (E. L. van Loon) and S. Diamond), 312—Preliminary report on treatment of asthmatic paroxysm with nicotinic acid (F. E. Maisel and E. Somkin), 691
Asthma and Hay Fever, Studies in (David Harley), 369
ATKEY, O. F. H.: Doctors as politicians and strategists, 483
ATKINS, H. J. B.: *After-treatment*, 99
ATKINSON, E. C.: Tetanus after sulphonamide treatment of cavities, 24—Urethral instrumentation, 111—Tonsillectomy: Guillotine or dissection? 620
Atropine, synthetic substitutes for, 256
Auscultation in non-penetrating abdominal injuries, 356
Auscultatory method, review of book on, 282
Australia: Brisbane, diphtheria immunization in, 109
Aviation medicine, bibliography of: review of, 545

B

Baby: for Mothers and Nurses (Mrs. J. Langton Hewer), 22nd ed., 697
BACHARACH, A. L. (and others): The herring as a source of vitamins A and D, 691 (O)
BACON, L. J.: Scabies, 260
Bacteria, sulphonamides and metabolism of, 134
Bactericide of plant origin, 349
Bacteriology, review of book on, 219
Bacteriology, Textbook of (R. W. FAIRBROTHER), 697
Bacteriophage for bacillary dysentery, 25, 81, 676
BADCOCK, V. E.: Diagnostic sign in ruptured pelvic ulcer, 472
BADGER, C. W.: Coltsfoot, 270
Bagassosis: An industrial lung disease (L. I. M. Castleden and J. L. Hamilton-Paterson), 478 (O)—Further notes of four cases (J. A. Gillison and F. Taylor), 577 (O)—In Parliament, 741
BAGDASAROV, Prof. A.: Blood transfusion in U.S.S.R. 445, (O)
BAILEY, E. T.: Director stirrup, 42
—— Hamilton (and F. E. C. DEVEGNEY): Diverticulum of jejunum, 98—*Demonstrations of Physical Signs in Clinical Surgery*, 8th ed., 131—*Surgery of Modern Warfare*, Vol. II, 2nd ed., 396—*Pye's Surgical Handicraft*, 545
—— K. Vernon: A light trailer ambulance, 296
BAIRD, D.: Stillbirth and neonatal mortality, 525
BAKER, John R.: Scientific journals for enemy prisoners of war, 768
BALFOUR, K. C. (and W. F. VIRET): Tietze's disease, 297
BALME, Harold: Fallacies concerning rehabilitation, 466—Rehabilitation centres, 589
Banerjee, Capt. Prabhas Chandra, death of, 56
BANETH, B.: Aspirin for asthma, 4[illegible]2
BANNISTER, M.: Obscure cause of haematemesis, 97
BARBER, C. H.: *Tropical and Sub-Tropical Diseases*, 247
Barbers Company elections, 355
BARCLAY, James A.: Crush injury and anoxia, 588
BARCROFT, Sir Joseph: Dehydration of foods, 255
BARFORD, J. L.: Artificial respiration in phosgene poisoning, 148
BARKER, J. (and L. W. MAPSON): Dehydration of foods, 255
—— P. B. (and C. DONALD): Louse-borne typhus fever 333, (O)
BARLOW, Sir Thomas: Royal Medical Benevolent Fund Christmas gifts, 454, 650
BARON, Cyril: Reporting of deaths to coroner, 739
BARTLEY, A. H.: Anaesthetic death in doctor's surgery, 170—Correspondence, 263, 351
—— W. C. (and others): Treatment of scabies, 1 (O)
BASHFORD, Guy R.: Demand on the blood donor, 440
BATE-SMITH, E. C, (and others): Dehydration of foods, 254
BATEMAN, C. H.: Planning Commission's Report, 53
—— Godfrey, obituary notice of, 114
—— W. Hirst: Treatment of plantar warts, 158—Correspondence, 300
BATT, Bernard E. A.: Convalescent serum and sulphapyridine in poliomyelitis, 189—Medical planning: the main issue, 321
Batten, George Beckett, obituary notice of, 145
—— Lindsey: *Health for the Young*, 515
BAUWENS, P.: Present and future status of physical medicine, 586
BEADNELL, L. M. M.: Breast-feeding, 4[illegible]9

THE TREATMENT OF SCABIES

BY

KENNETH MELLANBY, Ph.D., Major C. G. JOHNSON, R.A.M.C., and W. C. BARTLEY

A great deal of confusion exists concerning the best methods of treating scabies.* Every method has its advocates or detractors. Much of this confusion is caused by inaccuracies in diagnosis of infection and inaccuracies in assessment of cures. At the present time the disease is in the public eye, and many irritating skin conditions unconnected with *Sarcoptes* are apt to be diagnosed and treated as scabies, though, on the other hand, mild cases are often overlooked. Scabies can only be diagnosed with certainty when the mite *Sarcoptes scabiei* can be demonstrated or, at least, an unmistakable burrow seen. Another difficulty arises in assessment of cure. Many treated cases still show signs of extensive secondary impetigo or eczema even though the primary scabies has been cured. In such cases mild applications may cure the secondary complications and thus get the credit of curing scabies, which they are quite incapable of doing.

It is commonly believed that a long soak in a hot bath, followed by vigorous scrubbing, is an essential part of any scabies treatment and that this soaking and scrubbing will in itself often cure the disease. Results given below show that almost 100% of cases of scabies can be cured if efficient medicaments are used without any bath or scrubbing at all. If a well-established burrow is soaked and scrubbed, the brush can be applied vigorously to the lesion for as long as ten minutes without dislodging the parasite, and unless the scrubbing is severe enough to draw blood it is unlikely that many of the mites will be removed in this way. Really thorough scrubbing, often repeated, may sometimes cure scabies (Dixon, 1941), but this does not appear to be a practicable method for general use. Gordon and Seaton (1942a), from their work on *Notoëdres*, suggest that scrubbing may be an important preliminary part of scabies treatment. Their view is in part based on an examination of the lesions produced by *Notoëdres*; these are covered with scabs and dry exudate, whereas in human scabies live mites are seldom so protected. In spite of this, however, it is desirable that before applying a parasiticide the body should be soaked in a hot bath and rubbed well with soap, as this may enable the medicament to penetrate the skin more readily.

It is dangerous to assume that a patient has, or has not, been cured mainly because of the disappearance or otherwise of symptoms such as irritation. Some patients continue to itch for weeks after all parasites have been killed, while in other cases methods which we know to have practically no effect on the parasites will give at least temporary relief from irritation, especially if the patient believes they are efficacious. Many writers state that the methods they advocate will cure "resistant" cases which have not responded to other treatments. We have found no indication that the parasites are much more difficult to kill in some individuals than in others. There are, however, as stated above, considerable differences in the rapidity with which symptoms such as itching disappear; but a more potent acaricide does nothing to allay these symptoms—it may easily have the opposite effect.

In our experiments on the treatment of scabies we have assessed our cure primarily by an examination of the adult female mites removed from treated cases. We have developed methods by which we believe that over 90% of the ovigerous females can be detected. Samples totalling 1,200 mites removed from 441 cases suggest that about 90% of the ovigerous females seen on examining the skin are alive, the remaining 10% having died *in situ*. If only dead mites are found after treatment this suggests that the method is likely to be successful, but such results must be confirmed by a study of the relapse rate. Of 1,500 cases treated by us, approximately 1.7% had a recurrence of scabies; but as only three individuals relapsed within ten weeks we are probably safe in assuming that the recurrences were mainly reinfections. (Incidentally, a further 2.6% of patients returned apparently uncured a few days after treatment, but these were found to have no living *Sarcoptes* and merely a persistent itching, which gradually disappeared without further scabies treatment.) If, on the other hand, it is possible to find any live mites 24 hours after completing a treatment, this leaves no shadow of doubt that the treatment has not been successful. It should be noted that if even one live mite is left a recurrence of the disease is likely. It may take several weeks before the recurrence manifests itself fully, for this time must elapse before a reasonably large mite population can be built up again. Our results are based mainly on examination of the ovigerous females, but preliminary experiments suggest that the medicaments which kill these are also reasonably effective against the eggs. Incidentally, eggs killed with benzyl benzoate or sulphur seem to be "fixed" and remain normal in appearance when incubated; we therefore find it difficult to interpret Gordon and Seaton's (1942b) results, for they assessed the potency of drugs against *Notoëdres* by the percentage of eggs which degenerated after treatment. Nymphs, larvae, and adult males occur more superficially than females, and it seems unlikely that they will escape more easily. Timoney (1924) finds, with the *Sarcoptes* attacking the buffalo, that eggs are only slightly more resistant than adult females; all other stages are less resistant. We have also found that there is a very high mortality during development; if a proportion of live eggs are left deliberately they seldom give a reinfection. The chances of a reinfection where, say, 5% of the eggs survive are exceedingly remote in all but those cases with abnormally high populations of *Sarcoptes*.

Several times the advocates of a new method have suggested that it is much simpler than the old one because fewer applications of medicament are needed or because the bath and scrubbing can be omitted. These statements have been made without testing the old method to see whether it might also work under the simpler conditions. The main errors in assessment of scabies treatment have thus often led to an under-estimation of the efficacy of old methods, while at the same time the efficacy of certain new methods has been greatly over-estimated.

Details are given below of tests with most of the treatments in common use. In many cases the methods have been tried with and without baths and with and without any scrubbing of the usual sites of election. In all cases the whole body, from the neck down, has been treated with the medicament. The results are summarized in the Table. The numbers of mites found may require some explanation. We hope to publish elsewhere particulars of the numbers of parasites observed in cases of scabies, but may state here that on an average there were only 12 adult females. The majority of cases have less than this number, and a very small minority have over 50. The percentage of mites killed by any method is approximately the same whether only a few parasites are found on many patients or whether a large number of parasites are found on a single patient. During the later part of the experiments certain substances which we knew to be effective—e.g., sulphur ointment—were frequently used on cases irrespective of the parasite population, so that only rather small numbers of mites could be removed after treatment. With other methods of less-well-established efficacy, cases with high parasite count were chosen in order to obtain results quickly and to avoid a mass of work in treating or re-treating cases. All patients studied were adult males, but observations made on children and females do not suggest any considerable differences.

---

* A full summary of recent literature concerning treatment is given by Gordon and Seaton (1942a).

Sulphur Preparations

Sulphur Ointment (10% *Sulphur*).—Sulphur has been used since ancient times (see Hebra, 1868, for details) for the treatment of scabies, and sulphur ointment is a sarcopticide of proved efficacy. It has gained some notoriety because, when over-applied, a severe itching dermatitis is produced which is often thought to be due to a continuation of the parasitic infection. More ointment is then applied, with a further aggravation of the condition and, finally, disastrous results. The standard treatment consists in making three applications of the ointment, the first (and sometimes the second and third also) following a hot bath and scrubbing. Before our investigation reached the present stage, in which we can locate and extract most of the parasites, about 200 cases were treated by the above method without a single relapse being detected. In 147 cases since treated, the mites have been extracted after treatment. The results given in the Table show that a very high proportion of the mites were killed by one application, using approximately 3 oz. of sulphur ointment per patient. There is some indication here that the efficacy of the treatment is slightly enhanced by bathing and scrubbing, although the difference between the results (% killed) from the two types of treatment is not statistically significant. Even without bathing and scrubbing, very few mites survive, and two applications of the ointment have cured 100% of the cases. When skilled orderlies are available the disadvantage of the messiness of the treatment often outweighs the ease with which the medicament can be applied. We are of the opinion that sulphur ointment is likely to give more satisfactory results than other methods when used by the unskilled, for even if the ointment is carelessly applied there are chances of its spreading over a wider area than was originally covered. Adequate warning should be given against over-treatment. We have seen cases which have not been cured after using sulphur ointment for many days; these patients have been applying the ointment locally on the irritating areas. It cannot be too strongly stressed that the whole of the body except the head must be covered.

Sulphur Vanishing Cream.—In order to avoid the messiness of sulphur ointment and to economize in the paraffin base, vanishing creams containing sulphur, obtained through the kindness of the Cooper Technical Bureau, have been tried. The creams are very pleasant to use and do not soil the garments unduly. One containing 10% of sulphur appears to be as effective as the ordinary ointment. Further research is in progress to try to decrease the sulphur content; in 12 cases treated with a 0.5% sulphur vanishing cream the majority of the parasites were killed.

Marcussen's Ointment.—A commercial preparation of Marcussen's ointment called "kathiolan" was received through the kindness of Messrs. C. Zimmerman. It is claimed that this preparation will cure scabies within 24 hours, a contention which our experiments support. If applied as thickly as advised by the manufacturers, this ointment is even more objectionable in use than ordinary sulphur ointment, but if employed more sparingly it is equally effective and no more messy than the latter.

Flowers of Sulphur.—Flowers of sulphur dusted over a patient are said to give a simple and effective cure. The Table shows that though this treatment does kill some of the parasites it is relatively ineffective; for after 24 hours very few mites have been killed, and even after 3 days one-third of them are still alive. It should be noted that our patients have remained in bed in contact with the powder, 60 g. of which was used for each case. It seems likely that treatments of this kind result in a race between the production of a dermatitis and the extermination of the parasite. There is a real danger that the dermatitis may develop first.

Sodium Thiosulphate and Hydrochloric Acid.—It has been thought that if the sulphur could be released in nascent form it might be particularly effective. In this method the patient is first painted with a strong solution of hypo, which is allowed to dry. Some acid (i.e., hydrochloric) is then applied to the body; sulphur is released and conditions very harmful to *Sarcoptes* are alleged to arise. It should be noted that a patient who has been treated in this way is covered with yellow powder. This shows that the sulphur is deposited in rather coarse granules and not in a finely divided state, for in the latter condition the deposit would be white and not yellow. We find that one application of these solutions is hardly more effective than dusting with flowers of sulphur, and even after three applications a substantial proportion of the parasites remain alive. This method is troublesome to use, and the results are so unsatisfactory that we can see no reason for continuing with it. Moreover, it lends itself to zealous over-treatment.

Sulphur Lather Tablets.—Sulphur lather preparations have been used with apparent success in America (Nolan, 1938), and samples of a similar preparation ("sulfomil") were received through the kindness of Messrs. Glaxo Laboratories Ltd. In preliminary tests these appeared to give favourable results, for patients stated that the itching was greatly relieved and no sign of any dermatitis was produced. When, however, the effect of this preparation on the parasites was assessed with greater accuracy it was not found to be more effective in killing the *Sarcoptes* than the other medicaments which deposited sulphur powder on the skin. Even after three daily applications a substantial proportion (about 50%) of the parasites were still alive.

Sulphur taken Internally.—One of us has already reported (Mellanby, 1941) that sulphur taken internally appears to have no effect on *Sarcoptes* in the skin. Even if sulphur is taken in as large a dose as can be consumed without causing severe physical discomfort (10 g. daily for 10 days) the parasites appear to be entirely unharmed at the end of the period, and fresh mites can be induced to burrow normally.

Derris Root Preparations

Derris Root Lotion.—Rotenone, which is one of the active insecticidal products from derris root and some other plants, is known to be very effective in killing many species of insects. We are informed by the Cooper Technical Bureau that tests of rotenone-containing preparations against scabies in animals have given unsatisfactory results, although these products are highly effective against insect parasites on the same animal. Further, derris is notorious for causing dermatitis in man, and unless it has substantial advantages in the treatment of scabies its use is not one which recommends itself. The derris root lotion is essentially a suspension of derris root in water (4 oz. of derris root, 1 gallon of water, a small quantity of soap flakes). The results show that it is fairly toxic to *Sarcoptes*, but even after three days 21% of the mites survived and about 50% of the patients still harboured living *Sarcoptes*. This result is much inferior to that obtained by one application of sulphur ointment. Incidentally, we obtained derris root of known rotenone content through the Cooper Technical Bureau; samples bought in the ordinary way show considerable variations in strength.

Rotenone Emulsion.—A 2% emulsion of rotenone called "sarevan" advocated for the treatment of scabies was obtained through the kindness of Messrs. Evans Sons Lescher and Webb Ltd. It is interesting to compare the proportion of rotenone in this product with that found in other medicaments. The usual strength used in animal dips in veterinary practice is 1 in 16,000; the derris root lotion mentioned above contains approximately 1 part in 1,000; sarevan contains 1 part in 50! Notwithstanding this relatively enormous concentration we have not found sarevan outstandingly successful. A number of patients were treated with 4 applications, as recommended by the manufacturers, and a satisfactory cure was obtained, but some of them developed an intractable scrotal dermatitis. One application of sarevan still left about a quarter of the mites alive, so this method also was found to be much less effective than sulphur ointment.

Benzyl Benzoate

Benzyl benzoate is by no means a new treatment for scabies. It is the main active ingredient in balsam of Peru, which has been used for a very long time. Benzyl benzoate itself, in the form of "pernol," was advocated by Sachs and Juliusberg as long ago as 1900. This medicament was, however, first popularized by Kissmeyer, who in 1937 reported very favourable results from its use. Our conclusions support Kissmeyer's results, but we find that in unskilled hands, with insufficient supervision, benzyl benzoate lotion may be applied in such a way that some burrows are missed and relapses are apt to occur.

Benzyl benzoate lotion (25% benzyl benzoate, 35% soft soap, 40% spirit), the usual form in which this compound is applied, was found to be 100% effective, and equally satisfactory cures were obtained whether or not the patient was scrubbed. As there is some difficulty in obtaining soft soap and spirit, other benzyl benzoate preparations have been tried. A simple solution in methylated or industrial spirit was very effective, even as low a concentration as 10% benzyl benzoate killing 99% of the parasites. A solution containing only 5% proved less satisfactory, though more efficient than any other anti-scabies treatment except sulphur ointment. A solution in spirit is more difficult to use than the benzyl benzoate lotion as it is not easy to distinguish which parts of the body have been covered.

Results of benzyl benzoate emulsions in water have also been tried. Several different emulsifying agents, including lanette wax S.X., cellofas, and stearic acid with triethanolamine, have been found equally effective. An emulsion containing 10% of benzyl benzoate appears to be on the weak side, giving results closely resembling those obtained with a 5% solution in spirit. It should be noted that the emulsion goes considerably further than the spirit solution, only 2 fl. oz. being required to cover the body, as against 3¼ oz. of spirit solution. This means that approximately the same amount of benzyl benzoate is applied to the body with a 10% emulsion as with a 5% solution. A 20% emulsion appears to be completely satisfactory.

The National War Formulary gives a benzyl benzoate emulsion containing 25% of benzyl benzoate and 2% lanette wax S.X. The formula in the Appendix to this paper seems to us as efficient, and if many cases have to be treated it will effect important economies.

Other Sarcopticides

Dimethyl-diphenylene Disulphide (Dimethylthianthrene).—This substance, which was formerly marketed by Messrs. Bayer under the name of "mitigal," was obtained through the kindness of Imperial Chemical Industries Ltd. It is normally used undiluted on the body; it does not seem to produce any dermatitis or discomfort, and kills 100% *Sarcoptes* after one application. Unfortunately the substance is expensive in normal times, and at present is practically unobtainable. Preliminary experiments suggest that even when diluted down to 5% in medicinal paraffin it is still efficient. Work on dimethyl-diphenylene disulphide emulsions in water is now in progress.

Lethane.—Organic thiocyanates, such as lethane, are very effective against lice, and it has been suggested that they will also kill *Sarcoptes*. A 2% solution of lethane in medicinal paraffin appears to kill only about two-thirds of the mites after one application. Stronger solutions (i.e., 10%) cause the patient very considerable discomfort, and still are less efficient than benzyl benzoate or sulphur ointment.

Pyrethrum.—Various pyrethrin-containing substances have been tested. A commercial preparation containing pyrethrum extract in a petroleum jelly ("A.200") was obtained through the kindness of Messrs. Mitchell Cotts and Co. Later, substances of accurately determined pyrethrin content were prepared by Dr. J. T. Martin of the Department of Insecticides, Rothamsted Experimental Station, Harpenden. These tests do not suggest that pyrethrum extracts are particularly valuable against human scabies.

Betanaphthol.—Only two cases were treated with 10% betanaphthol ointment. Twenty-four hours after treatment 27 mites were removed; of these, 5 (18.5%) were alive. As only 2 live mites were removed from the 225 cases treated with 20% benzyl benzoate emulsion, it is clear that betanaphthol is a much less satisfactory medicament.

Discussion

The experiments described above indicate that of the treatments of scabies in common use two only, sulphur ointment and benzyl benzoate, are satisfactory. It is interesting to compare the *in vitro* reactions of *Sarcoptes* to these preparations. It is well known that the mite will survive for several days when stuck in sulphur ointment on a glass slide; we have confirmed this observation. Sulphur ointment appears to be effective only when some active products due to the interaction of the sulphur and the human body are liberated. Benzyl benzoate, on the other hand, is rapidly lethal to the mites, which are killed within five minutes of contact away from the body.

It should be noted that it is almost impossible for a patient to apply either liquid preparations or creams satisfactorily to himself; therefore, if it is not possible to get another person (preferably trained for the purpose) to apply these remedies, it is better to use sulphur ointment treatment.

APPENDIX: DIRECTIONS FOR PREPARATION OF BENZYL BENZOATE EMULSIONS

The following three emulsions containing 20% of benzyl benzoate have been found satisfactory. If a 25% emulsion is preferred this can be made by increasing the benzyl benzoate and decreasing the water in the appropriate quantities.

Benzyl benzoate	200 mils
Lanette wax S.X.	10 g
Water	800 mils

Melt the lanette wax on a water-bath, add the benzyl benzoate, and heat the mixture to a temperature of between 60° and 70° C Pour the mixture into the water, previously heated to the same temperature, and stir until cold.

Benzyl benzoate	200 mils
Stearic acid	20 g
Triethanolamine	5 mils
Water to produce	1,000 mils

Melt the stearic acid with the benzyl benzoate on a water-bath. Mix the triethanolamine with half the quantity required of warm water, and pour into the stearic acid–benzyl benzoate mixture cooled to about 30° C. Shake to form an emulsion Add enough water to produce the required volume.

Benzyl benzoate	200 mils
1% solution of cellofas W.F.Z.	800 mils

Shake together to form an emulsion. Put through a cream-making machine or homogenizer.

NARCO-ANALYSIS IN THE TREATMENT OF WAR NEUROSES

BY

J. F. WILDE, M.D., D.P.M.
Major, R.A.M.C.; Psychiatric Specialist

Many and diverse are the methods that have been used in exploring the meanderings of the neurotic mind. In the early days of psycho-analysis Freud (Breuer and Freud, 1893) employed hypnosis in overcoming the resistance of his patients, and, later on, in his dream analysis utilized the recurrent narcosis of natural sleep. However, the methods of psycho-analysis and all its derivatives are intricate and require considerable skill, time, and special training. In war the problem of having to deal with greater numbers of neurotics in the Services compels the profession to improvise less intricate and more rapid techniques. During the war of 1914-18 Hadfield's (1920) technique of hypno-analysis was most effective. Since 1929, research in the use of drugs as an aid to gaining insight into and rapport with patients suffering from mental and nervous illness has been in progress.

The drugs which are most useful for this purpose are the barbiturates. Bleckwenn (Lorenz, 1930) of Wisconsin, in 1929, was the first to use sodium amytal in an endeavour to gain closer rapport with his psychotic and psychoneurotic patients. Nembutal appeared in 1930, evipan in 1932, and pentothal in 1934, and these drugs have since been freely used. Other drugs that have been experimented with include cocaine, hashish, and mescaline (Lindemann and Malamud, 1934), alcohol, and medinal and paraldehyde (Hauptmann, 1934). Workers in this field also include Stungo (1938) and Campbell (1938), who employed evipan, Mallinson (1940), who has published an account of its use in the Royal Navy, and Dicks and Stungo (1940) and Sargant and Slater (1940), who have reported their experiences in the E.M.S.

The term "narco-analysis" was first devised by J. S. Horsley (1936) for the technique which utilizes a narcosis artificially induced by a barbiturate for the express purpose of facilitating the analysis of a patient's mental content. The barbiturates employed are those which have proved so useful as intravenous anaesthetics. When used as narcotics the dose is of course much smaller. In this respect it is of interest to note that hypnosis, which is the essential preliminary to hypno-analysis, was first employed in orthodox medicine as an anaesthetic by Elliotson, Esdaile, and Braid (Bramwell, 1913) for surgical operations before the discovery of chloroform or ether.

The Present Investigation

Fifty soldiers suffering from neuroses were treated by this method. The drug used was pentothal sodium—sodium ethyl (1-methyl butyl) thio-barbituric acid. It is similar in action to sodium amytal and nembutal, but safer in that it is less toxic and more readily eliminated. It is a respiratory depressant and lowers blood pressure temporarily, and is detoxicated by the liver, but has no effect upon the kidneys, so the only physical contraindications to its use are respiratory disease, low blood pressure, and liver embarrassment. These were rarely met with in healthy young neurotic soldiers. It should not be used in varicose veins if this can be avoided, because of the probability of delayed phlebitis.

Indications for Narco-analysis.—When a neurotic is admitted to hospital it is first of all essential to take a complete psychiatric history. Next a physical examination is conducted and any necessary physical treatment given. Although this has usually been done before the soldier reaches a psychological unit, it is surprising how physical signs are sometimes missed by physicians and surgeons of repute, doubtless because during their examinations the display of some gross functional symptoms by the patient has biased their judgment against a physical diagnosis. Next follow several psychological interviews in which one endeavours to explore the motives behind the symptoms. It is important to be in possession of all the facts of which the patient is consciously aware. If an impasse is reached in which the patient, though trying his best, cannot honestly remember the painful matters that have been repressed, and if this repression remains impervious to all psychotherapeutic efforts quickly applied, then one resorts to narco-analysis. It is explained to the patient simply that he will be given an injection to help him to get better. It will make him sleepy, but will have no untoward after-effects. Soldiers are at liberty to refuse injection, so it is necessary to win their approval by persuasion. At times all sorts of wild rumours have been current in the wards to the effect that (*a*) the injection will weaken the patient's will power, (*b*) under it they will be forced to say everything they wish to keep secret, and (*c*) every word uttered will be taken down by a stenographer and afterwards used in evidence against them. At times such rumours have prevented me from having a case to treat in this way for months on end, and then a few successful cases make the technique popular again.

I have found intravenous sodium pentothal of assistance in (1) hysteria in its various manifestations; (2) anxiety states; (3) the after-effects of head and spine injuries; (4) borderline psychoses, mental deficiency, and epilepsy when the diagnosis was in doubt; and (5) simulation and malingering.

Administration of the Drug.—The time chosen for injection is about 2 hours after a meal. The patient is made comfortable on a couch or bed in a quiet room and is reassured. The collar and belt are loosened and the median basilic vein is prepared for venepuncture. An ampoule containing 0.5 g. (7.5 gr.) of sodium pentothal is opened and dissolved in the barrel of a

TABLE I.—*Patients in whom the Hysterical Reaction was Predominant*

Case No.	Symptoms	Effect of Pentothal	Result
1	Amnesia, dyspepsia, vomiting	No euphoria. Dramatic abreaction of war experience Revelation of unrequited love affair prior to service	Duty
3	Vague pains left shoulder, hip, and leg	No euphoria Very depressed reaction, though talkative	Invalided
4	Deafness and aphonia	Marked euphoria. Relief of deafness and aphonia, revelation of detailed history	Duty
5	Anxious about eyesight	No euphoria. Depressed and lacrimose Revealed that the symptom complained of was not real trouble	"
8	Amnesia	Not euphoric, but loquacious. Memory recovered Motive underlying fugue revealed to be domestic worries	"
9	Pain in back and insomnia	No euphoria. Maniacal reaction to physical injury received nine years ago	"
10	Sequelae of head injury	No euphoria. Unemotional account of war experiences. No head injury actually occurred. Later wept bitterly	"
13	Pain in back	Euphoric and talkative. Revealed domestic situation in civil life as root of his trouble	Invalided
18	Amnesia following head injury	Euphoric; spoke freely, but in French Revealed that no actual head injury occurred	Duty
22	Vague rheumatic pains	No euphoria. Vivid revelation of war experiences	"
23	Depression with suicidal impulses	No euphoria. Unemotional revelation of domestic situation When fully conscious, convulsive sobbing	Invalided
24	Head-wagging tic	Not euphoric; serious. Revelation of fear of which he was unaware before	Duty
26	Head injury, amnesia, war dreams	Euphoric. Memory restored. Sequelae relieved	"
27	Constant headaches	Not euphoric; lacrimose. Personal problems revealed	"
28	Recurrent fugues	Not euphoric. Resistance not overcome	Invalided
30	Amnesia	Not euphoric, but uninhibited. A temperamentally unstable subject simulating amnesia	Duty
32	Anxious about eyesight. Depressed and apathetic	Not euphoric, but emotional. Family troubles revealed. Eyesight not improved, but depression relieved	"
35	Amnesia	Not euphoric, but emotional. Memory restored	"
36	Head injury. Persistent headaches, amnesia	Not euphoric. Memory restored. Symptoms relieved	"
38	Violent nightmares	Not euphoric. Traumatic episode revealed	"
41	Hysterical tic	Euphoric. Domestic situation associated with tic brought to light	"
42	Hysterical fugue	Mere suggestion that injection could restore his memory caused him to reveal that injury was consciously self-inflicted	"
49	Anaesthetic corneae	No euphoria. Psychotic, but sensation of corneae restored	Invalided

TABLE II.—*Cases in which Anxiety Predominated*

Case No.	Symptoms	Effect of Pentothal	Result
2	Insomnia, anorexia, trembling	Euphoric, aggressive, communicative. Revealed important personal and family secrets	Duty
12	Multiple healed wounds and stammer	Euphoric and loquacious. Speech clear. Revealed important nuclear incident	"
14	Morose and reticent	Not euphoric; emotional and agitated. No new revelations	Invalided
16	Trembling and emotional	Not euphoric. Revealed a strong maternal attachment from childhood	"
19	Palpitations. Pain in back	Not euphoric. Communicative about Quetta earthquake and instability at home	"
25	Confused, irritable, unable to concentrate	Not euphoric, but agitated and expressed great feeling of guilt for shooting up enemy	Duty
29	General pains. Poor memory and lack of concentration	Not euphoric. Amnesia recovered	Invalided
31	Insomnia, anorexia, amnesia	Not euphoric. Memory recovered. Revealed a fear of showing fear	Duty
33	Insomnia, war dreams, anorexia	Not euphoric. Recorded all experiences for the first time	"
40	Fears loss of vision. Amnesia	Not euphoric. Revealed that real trouble was domestic worry	"
43	Frequency of micturition	Not euphoric. Disclosed factors underlying origin of symptom 10 years ago and repeated now	"
44	Nightmares and nervousness	Not euphoric. Disclosed unsuspected emotional reaction to earlier incident and a fear of showing fear	Invalided
45	Faints and palpitations	Not euphoric. Conditions causing his anxiety shown to be unconnected with war trauma	Duty
47	Headaches and insomnia	Not euphoric. Emotional and abusive, but freely informative about his war experiences	"
48	Diarrhoea, blood in stools. Flatulence	Not euphoric. Related with marked emotion important personal experiences prior to his war trauma	"
50	Enuresis	Not euphoric. Personal experiences prior to war revealed as chief worries	"

TABLE III.—*Cases in which there was a History of Head Injury*

Case No.	Symptoms	Effect of Pentothal	Result
10	Chronic headaches, nervousness, irritability	Not euphoric. Unemotional account of war experience. No head injury actually occurred	Duty
18	Amnesia	Euphoric; spoke freely in French. Revealed that no actual head injury occurred	"
26	Amnesia, war dreams	Euphoric. Memory restored. Sequelae relieved	"
34	Depression, dizziness, trembling	Not euphoric; displayed fear and anger. Seemed to be relieved of his fear of pain	"
35	Headaches, lassitude, tremors, palpitations, depression	Not euphoric. Memory restored. Revealed fear of showing fear	"
36	Headaches, amnesia	Not euphoric. Memory restored. Symptoms relieved	"
39	Headaches, dizziness, general lassitude, amnesia	Not euphoric. Memory for events immediately following head injury recovered and later corroborated. Symptoms relieved	"

TABLE IV.—*Illnesses Predominantly Physical*

Case No.	Symptoms	Effect of Pentothal	Result
11	Complete bilateral deafness	Deafness quite unaltered by pentothal	Invalided
15	Deafness	Deafness not relieved under pentothal. E.N.T. specialist decided it was nerve deafness	"
20	Hysterical reaction to spinal injury	Memory recovered under pentothal. Further treatment refused because of its implications	"
46	Excessive reaction to physical injury	Was able to re-experience the emotions associated with original injury	Duty

TABLE V.—*Miscellaneous Group*

Case No.	Symptoms	Effect of Pentothal	Result
6	Amblyopia right eye, blepharospasm left	Euphoric. Blepharospasm relieved. Diagnosis of mental deficiency established	Invalided
7	Severe stammer	Not euphoric. History obtained only by means of pentothal	Transferred
17	Epilepsy ?	Evidence of maternal attachments revealed. Suspected that he was making the most of his symptoms to obtain discharge from the Army	Duty
21	Deafness (functional)	Not euphoric, but revealed a history of depression with family history of suicide on both sides	Invalided
37	No symptoms	Not euphoric. Story of war injury revealed to be false Psychopathic personality	"

10-c.cm. syringe in chemically pure water that has been specially supplied in a sealed ampoule. This makes a 5% solution. The injection is then administered very slowly, giving only 1 c.cm. per minute (checked by the second hand of a watch). The patient is asked to count from the very first, and when he reaches 100 and is getting drowsy he is asked to count back. Very few patients have required the full 10 c.cm. This is in marked contrast with the amount required for anaesthesia, in which the dosage ranges from 0.1 to 3.4 g. for operations varying in duration from 5 minutes to 4 hours or more. In no case have I used more than 0.5 g. In the earlier cases of this series my aim was to produce a very short period of unconsciousness. However, I soon found it preferable to give a much smaller dose, so that the patient did not get so far as unconsciousness, but was drowsy and had not quite reached the stage of incoherence. Anything from 0.25 to 0.4 g. was sufficient for my purpose, depending on the individual response of the patient.

Complications.—Central respiratory paralysis with subsequent circulatory failure, if threatened, should be dealt with by artificial respiration, oxygen and CO_2 inhalation, and the administration of coramine or picrotoxin.

Results

The mortality and morbidity in my series of 50 cases was *nil*. Tovell records 6 fatalities out of 4,000 anaesthetic cases. Cameron had one fatal case in 225—that of a very fat diabetic negress who required amputation of a toe for gangrene. Our group, which was unselected, included every soldier that came under my care over a period of 13 months whose investigation was held up by resistance and who, at the same time, was fit physically to receive pentothal and could be persuaded to submit to the treatment.

Of these patients 35 showed predisposition to neurosis prior to service; 31 had suffered actual war trauma. Of the 50 patients treated in this way 33 were rendered fit for duty and 17 were invalided. About half those invalided were fit to return to good posts in civil life. In fact, in some the pronounced secondary advantage of having a good position in civil life to which to return was a factor mitigating against successful removal of the neurotic symptom.

Illustrative Case

Case 26.—A soldier, aged 33, who had been in the service for 18 months, was admitted to hospital complaining of frequent nightmares associated with war dreams and general nervousness. Four months previously he had been exposed to bomb blast and had been rendered "unconscious" for 36 hours. Amnesia for those 36 hours was complete. He had had a normal school and work record, was the second son in a family of 6 boys and girls, was happily married, and happy in his unit. No family history of mental or nervous illness was elicited. On clinical examination there were no physical signs of disease apart from coarse tremor of the limbs and somewhat exaggerated reflexes. He was considered to be a case of hysterical amnesia and suitable for narco-analysis. It was thought essential first to relieve his amnesia. He reacted extremely well to a small injection of pentothal (5 c.cm.), and became euphoric and excessively loquacious. Amongst other things he related how he had been on the verge of "a sensual indiscretion," about which he felt extremely guilty, immediately before the air raids in which he was injured. He recalled the bombing and recounted how he was thrown down violently and covered with mud, how his friends came and had him admitted to hospital, and all the details of the way the nurses and doctors dealt with him on admission. All this was confirmed later. He made an immediate improvement; he was able to recall all these experiences when he came round from the influence of the drug, and seemed to fear them no longer. For the remainder of his stay in hospital he was symptom-free and a good advertisement for other similar patients, persuading them to submit to the same therapy. He returned to duty.

The cases are presented in tabular form. Table I deals with the patients in whom the hysterical reaction predominated. Table II summarizes the cases in which anxiety states predominated. Table III deals with 7 cases with a history of head injury. Table IV deals with 4 patients whose illness was predominantly physical. Table V contains details of a miscellaneous group. The number in the first column refers to the chronological order in which they were treated. In many of the cases accurate diagnosis has been difficult, because it was found that for the most part they did not fit clinically the classical descriptions—e.g., patients predominantly hysterical in their reactions showed anxiety symptoms, and obvious anxiety neurotics at times displayed hysterical features. Again, apparent neurotics under narco-analysis revealed themselves as psychotics, and certain sufferers from physical injury displayed superimposed neurotic features.

Discussion

The advantages of this simple physical approach to the intricacies of psychological mechanisms are that it is safe, rapid, and sure: the mortality, inside the wide limits imposed by contraindications and using the small doses of pentothal advocated, is *nil*. It is a much more rapid approach to the factors hidden behind neurotic symptoms than any other form of psychotherapy except hypno-analysis, and the necessity for the services of a skilled hypnotist is eliminated. It is a sure method of getting a patient into a narcotic state without unpleasant after-effects, and the required degree of narcosis can be achieved to a nicety with very little practice by giving the injection extremely slowly, as described, and conversing with the patient all the while.

One disadvantage is that it is technically an operation: in the Army a soldier can refuse any injection or operation, and very often exercises this privilege. Rumours about the mysteries and dangers of narco-analysis are reminiscent of former outcries against the use of hypnotism and anaesthetics. Another disadvantage of making a physical approach to a neurotic patient is that he may revert to the belief that some physical defect is still responsible for the illness and persist in avoiding the psychological issue in spite of all physical examinations having proved negative.

Narco-analysis with intravenous barbiturates is not a method which at present is universally successful in overcoming resistance. There has been a good deal of irresponsible Press publicity, principally in the United States, about the use of intravenous barbiturates as "truth serum," but I have been able to trace only one scientific article on the subject in the medical literature. In this Lorenz (1932) refers to the undue Press publicity, and states that the medical profession, in its contact with the public, should seek to correct the misinformation that prevails. In the 3 cases he quotes the patients who were suspected of murder were, under the influence of sodium amytal, able to establish their innocence.

Dr. Emanuel Miller in a private communication has informed me that he was called upon to give evidence before a court martial in defence of a soldier whom he had treated for a hysterical fugue. He had used evipan narcosis in his treatment, and the material obtained from the accused by this means was accepted as evidence by the court. It is debatable whether material so obtained should ever be accepted as evidence *against* any accused person. Though memory was restored under pentothal narcosis in a number of my patients suffering from amnesia, and the material thus recovered was corroborated independently afterwards, I am not prepared to say that the truth is always revealed. The patients with whom I had success were co-operative so far as they could be, and had something to gain by being communicative when assisted by injection. No doubt, in time, this technique may be perfected so that one can be sure whether the truth is being revealed or not, and this will be a great medico-legal advance, but from the psychotherapeutic standpoint it is not so important to be sure that the repressed material is absolutely true. The hidden fears of the neurotic may be sheer fantasy and the wildest confabulations of imagination. They are none the less terrifying, perhaps more so than real dangers. Yet these fantasies are the phenomena with which we as therapists have to deal in helping our patients to adjust themselves to themselves and to their hidden fears.

The phenomena observed in the 7 cases with a history of head injury give rise to interesting speculation. Two of these, under investigation, revealed that no head injury had ever occurred; but, even in those in which there was no doubt about physical injury, restoration of memory and abreaction was followed by relief of the sequelae. It may be that in these cases there was no real brain injury and that they were similar to cases of other bodily injury followed by hysterically exaggerated symptoms. It is a type of injury which would repay further exploration by this method. All these men were returned to duty.

It will have been noted that a great number of these so-called war neuroses when subjected to narco-analysis revealed hitherto unsuspected data. In many of them the hidden worries brought to light had nothing whatever to do with the war, the trauma experienced in fighting being only the precipitating factor in predisposed subjects. Patients are often more ready to talk of their war experiences than they are to confide their personal and domestic worries. But it is usually the revelation of the things they least want to talk about that brings relief of neurotic symptoms. The clinical study of these soldiers suffering from neuroses has exemplified that the factors underlying both war and civilian neuroses are similar. But the war has precipitated these neuroses, and we are faced with the problem of having to deal with great numbers of psychoneuroses in the Army, in which saving of time in treatment is very important.

All sufferers from neuroses find it difficult to confide entirely in their doctors. For those in civil life who can choose their own doctor this difficulty may be somewhat diminished, but for the hospital out-patient and the soldier faced with a medical officer in uniform there is virtually no choice, and thus treatment in the ordinary way tends to be either prolonged or ineffectual. The progress made in the Services towards perfecting the technique of narco-analysis during the war will be invaluable when tackling the problem of civilian neuroses in the period of post-war reconstruction.

POSTURING IN BRONCHOGRAPHY

BY

F. DUDLEY HART, M.D., M.R.C.P.

Medical Officer, E.M.S.; Medical Registrar, Westminster Hospital

In a study of the literature on bronchography one is struck by two things: first that methods of introduction of lipiodol into the bronchial tract are discussed at great length though little detail is given of posturing the patient to fill different areas of the lung; secondly, that the radiographs illustrated often show large areas unfilled. If one is demonstrating a basal bronchiectasis it is essential to exclude the same disease elsewhere if operation is contemplated. The right, middle, or left lingular lobe is also frequently unfilled, and, though all zones appear on rapid inspection of an A.-P. film to be filled, closer inspection will show that the middle-lobe bronchi are empty of oil, a fact brought out readily in a lateral view. As bronchography is primarily an investigation to locate lesions and to define their extent exactly, it is as important to know what areas are normal as to know what areas are abnormal. To outline the bronchial tree completely on one side of the chest is therefore essential, and to do this with certainty proper posturing is required as described by Erwin (1936).

Technique

It was found best to adopt a standard technique and vary it hardly at all. Assistant and radiographer should be well acquainted with the different stages so that the investigation can be performed without any waiting periods. The patient should be prepared by posturing and/or premedication if necessary, and should have been tested for iodine and cocaine sensitivity.

The Two-stage Method

By this method only one side of the chest is outlined at one sitting. The patient lies on the *x*-ray couch, with head and shoulders raised approximately 30 degrees on several pillows, the chin elevated, and the head thrown back. A bleb of 2% procaine is produced in the skin over the crico-thyroid membrane: only a few minims (6 to 12) of local anaesthetic are required, as more tends to cause haematoma formation. If cocaine is necessary some 5 minims of 5% cocaine hydrochloride is injected rapidly into the trachea, the needle being rapidly withdrawn. The patient sits up, coughs several times, then returns to exactly the same position as before. He is cautioned not to swallow or cough from this time until the radiographs have been seen and approved. The iodized oil—lipiodol (Lafay) or neohydriol (May and Baker)—is then injected through the anaesthetized area after heating it to just above blood heat in a water bath, the patient being rotated so that the opposite shoulder is raised several inches. This prevents the oil from running into the opposite main bronchus. After some 8 to 10 c.cm. has been injected the patient places his two hands on the investigator's shoulders, lifts himself to a sitting position, still leaning over to the affected side, and leans forwards and sideways so that his body is almost parallel with the floor. The investigator is now kneeling by the side of the couch, the patient's hands on his shoulders, the patient's face looking down into his. In this position 6 to 8 c.cm. of oil is run into the middle lobe. After 1 to 2 minutes the rest of the oil (6 to 8 c.cm.) is injected. The needle withdrawn, the patient quickly lies on the affected side, and the foot of the table is rapidly elevated. As his head sinks below his heels he moves half over on to his face, still lying on the affected side.

In this way the lung has been filled in all its zones, the bronchi of the "four fundamental lobes"—dorsal, middle, upper, and lower—being outlined on the affected side. If successfully done no oil has spilled over on to the opposite side and none has regurgitated into the mouth (though this cannot be prevented in all cases). Radiographs, A.-P. and lateral, are now taken. If the upper zone is mainly under suspicion the patient is kept in this position, with the head low, and radiographed. If the middle lobes are suspected particularly, the foot of the table is depressed so that the feet are a little lower than the head. A lateral picture is taken in this position, the patient lying on the affected side, and a P.-A. film with the patient on his face. If it is required to outline the basal bronchi particularly, lateral and A.-P. pictures are taken with the patient erect. In all cases he is kept in the same position until the films have been seen and passed, further views being taken as found necessary. Screening is then performed with the patient in the erect position. The opposite side of the chest is filled in the same manner some 7 to 10 days later.

One-stage Methods

If it is required to outline both sides at one session one of the following methods may be adopted.

1. Technique as above, using rather less oil; so that instead of a total of 20 to 25 c.cm. only some 14 c.cm. is introduced into the side under suspicion. Films are taken in the required position as described above. The remaining 8 to 12 c.cm. of oil is then introduced into the opposite lung with identical posturing, A.-P. and oblique views being taken. The disadvantage here lies in the reintroduction of the needle into the neck.

2. Technique as above, one side being completely filled and films taken A.-P. and lateral in the required position. If the patient has had the left side filled he turns on to the right, and the head of the couch is lowered for one or two minutes. The oil now runs from the left base into the right upper lobe bronchus. The couch is returned to its first horizontal position and the patient leans over the right side of the couch, with his body almost parallel with the floor, to fill the middle-lobe bronchus as described previously. In so doing some oil runs also into the lower-lobe bronchus. He then sits upright again, leaning slightly over to the right side, and more oil runs down into the basal bronchi. Screening is now performed, erect or prone, and if sufficient oil has not passed over into the second

side the posturing is repeated. It is necessary, however, to perform the whole manœuvre with as little delay as possible, as the oil becomes rather more viscid as it cools. Alternatively, the oil may be rendered thinner by the addition of olive oil (4 to 6 c.cm. of olive oil to 20 c.cm. of neohydriol or lipiodol), it being introduced without any preliminary heating. This, however, does not always give satisfactory results, as the thinner oil runs in the smaller bronchi and is there retained. By this posturing the patient is spared reintroduction of the needle into the neck, and excellent pictures can be obtained (Figs. 1 and 2) —A.-P. and lateral of the side first filled, A.-P. and oblique after filling of the second side.

Subsequently, whatever method is used, the patient is told to expectorate as much as possible and not to swallow any sputum. If necessary he should posture to get rid of iodized oil from any cavities where it may have lodged. Oil seen on screening in an iodine-sensitive patient's stomach should be removed by stomach wash-out or administration of emetics. A patient who has received cocaine should be warned not to eat or drink for three hours subsequently.

Discussion

The crico-thyroid route has been used merely because I get the best results with it, and because cocainization can be cut down to a minimum in all patients and omitted in many. Sensitivity below the vocal cords to injections seems to vary greatly, and many patients can control their cough reflex without cocaine anaesthetization (Jewesbury, 1939). Be that as it may, transnasal, translingual, or other routes may be used if preferred. The importance is stressed not of the site of introduction of the oil but of the areas reached after introduction. A lateral view of the affected side is essential, and, if posturing be faulty, oil on the opposite side will render this view confused, one bronchial tree being superimposed on the other in the film. To fill the middle lobe properly is also essential, and lateral views are again necessary. The hard-pressed radiologist should be spared the pain of reporting yet again: "Those few basal bronchi outlined are normal."

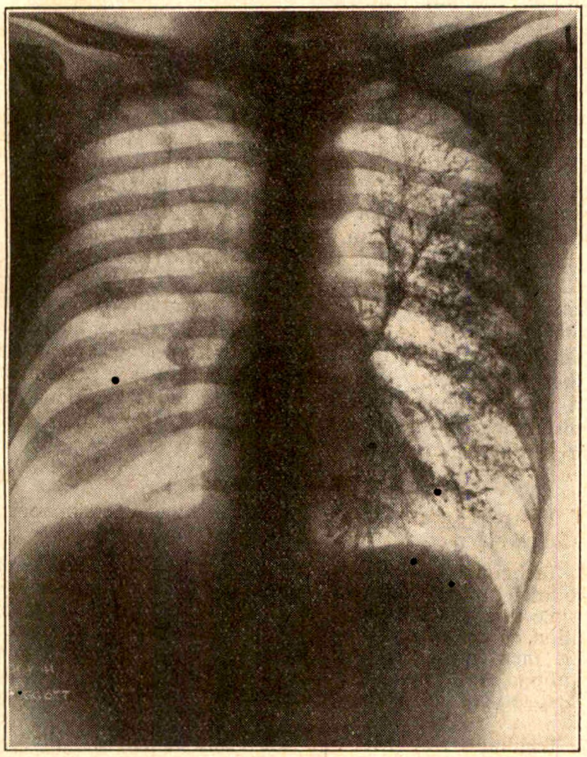

FIG. 1.—Radiograph showing outlines of the left side of chest.

Summary

The importance of adequate posturing on bronchography is stressed, and a standard technique is described which allows delineation of all parts of the bronchial tree. Without such technique, imperfect filling of the bronchial tree will be the rule instead of the exception.

My thanks are due to Drs. W. E. Lloyd and W. H. Coldwell for their kindness and help, and to the Sister and staff of the *x*-ray department, Westminster Hospital.

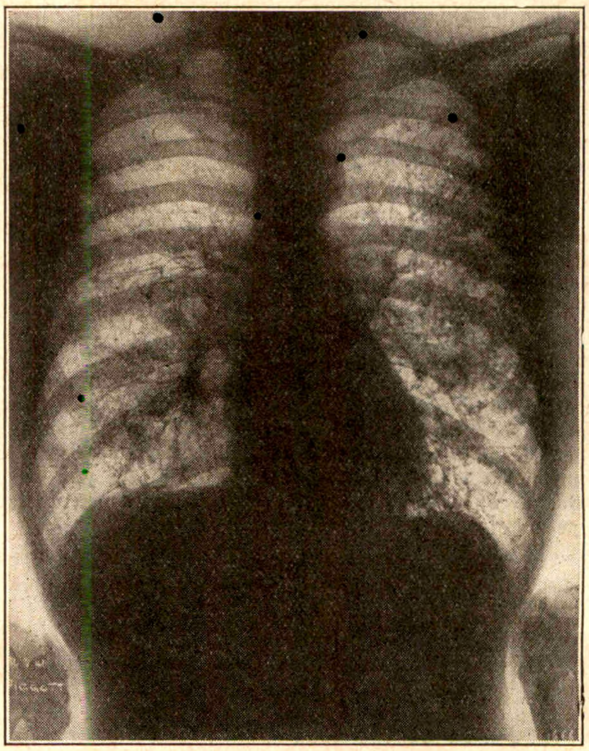

FIG. 2.—Right side outlined by posturing the patient. The oil from the left side has been made to run over and outline the right.

THE EFFECT OF BLEEDING ON THE BLOOD-SUGAR LEVEL IN BLOOD DONORS*

BY

B. J. LAWRENCE, M.B., Ch.B.

AND

G. PLAUT, M.D.

The object of the present investigation was to determine whether the level of the blood sugar is related to the incidence of "fainting" in blood donors. The clinical characteristics of such faints have been previously described by Brown and McCormack (1942). Certain factors responsible have been analysed by a statistical survey (Greenbury, 1942). In the latter it was suggested that lack of food might be a predisposing cause. If a constant low blood-sugar level occurred in donors who fainted, as opposed to those who did not, it would favour such a hypothesis.

Method

In a series of 50 unselected donors blood-sugar estimations were made upon samples of capillary blood obtained from the ear immediately before and immediately after the withdrawal of between 400 and 450 c.cm. of blood by the Medical Research Council technique (Brown and McCormack, 1942). In a second series of 46 unselected donors blood-sugar estimations were made upon venous blood taken at the end of a routine bleeding from the antecubital vein. In these cases a pressure of between

---

* A report to the Medical Research Council from the N.W. London Blood Supply Depot.

60 and 80 mm. Hg had been maintained by a sphygmomanometer cuff on the arm for 3 to 5 minutes before the sample was obtained. During this period, in order to facilitate the blood flow, the donor had continuously clasped and unclasped a rolled bandage held in the palm of the hand. All samples were collected in small bottles containing dried oxalate (equivalent to 1 c.cm. of a mixture of 1.2% ammonium oxalate and 0.8% potassium oxalate). Owing to the nature of the transfusion service it was not possible to standardize conditions of temperature, previous exercise, or the time of the last meal. The majority of donors had had a meal within 3 hours of venesection.

The method used for the estimation of glucose was Harding's modification of the Schaffer-Hartmann method as described by King, Haslewood, and Delory (1937).

Results

In the series of 50 unselected donors examined before and after bleeding only 2 fainted. Their blood-sugar levels were 85.8 mg. and 98.6 mg. per 100 c.cm. before and 85.8 and 100.92 after bleeding. The findings in the other 48 donors are summarized in Table I. No change in blood-sugar level was found in 13 instances; in 27 there was a slight increase after bleeding, the average figure being 16.34 mg., while in 10 there was a decrease of the same order. In the second series of 46 unselected donors in whom the level of the blood sugar in venous blood obtained at the end of bleeding was determined, 16 fainted either while being bled, so that the full amount could not be withdrawn, or immediately afterwards. The results are summarized in Table II. Again the figures recorded reveal no significant difference in the blood-sugar level of donors who faint and those who do not.

TABLE I.—*Capillary Blood-sugar Values*

Time	No. of Donors	Blood-sugar Values in mg. per 100 c.cm.	
		Range	Mean
Before bleeding ..	48	60·32 to 100·40	94·91 ± 6·12
After bleeding ..	48	67·30 to 147·32	100·67 ± 6·56

TABLE II.—*Venous Blood-sugar Values*

Donors	No. of Donors	Blood-sugar Values in mg. per 100 c.cm.	
		Range	Mean
Group 1 (normals)	30	28·01 to 106·42	66·14 ± 7·14
Group 2 (faints) ..	16	50·11 to 100·33	77·27 ± 5·90

There was no apparent relation between the age of the donor and the blood-sugar level. One extremely low figure of 28.01 mg. occurred in an old man of 73 who had had a good breakfast about 2½ hours before bleeding and who felt perfectly well. No correlation could be established between the time that had elapsed since the last meal, the blood-sugar level, and the incidence of fainting.

Discussion

The figures for the blood-sugar level recorded in the present investigation suggest that a low blood sugar is not a factor associated with fainting in blood donors, and that withdrawal of 500 c.cm. of blood does not result in any definite change in the blood-sugar level. The level in the first series, made upon capillary blood, was higher than that in the second series, made upon venous blood—a finding in agreement with that of other workers (Jonas, 1933; Himsworth, 1933; Shoji *et al.*, 1938). Shoji and his co-workers found that the contraction of the forearm muscles decreased the sugar content of venous blood considerably in non-fasting subjects. Such contraction of muscles occurs in all donors, as they are asked to clasp and unclasp their hands during the bleeding procedure in order to facilitate the blood flow. It is probably responsible for the rather wide difference observed.

Summary

The blood sugar was estimated in 96 donors, 18 of whom fainted. No significant difference was found in the level of the blood sugar after bleeding. This level was without effect upon the incidence of fainting.

CONDITION OF RETAILED RAW MILK IN AN URBAN AREA

BY

C. A. GREEN, M.D., Ph.D., D.P.H.
Surgeon Commander, R.N.V.R.

The incidence of tuberculosis of the bovine type in the human subject is regrettably high in this country. Bendixen *et al.* (1937) recorded aggregate figures which showed that the percentage frequency of this type in cervical gland infections at all ages was 46.2 and 52.3 in England and Scotland respectively. The corresponding figures in bone and joint infections were 22 and 29.8; in lung infections, 0.9 and 5.5; in lupus, 48.6 and 53.8; in meningeal infection, 25.7 and 29.8. Lesions due to the bovine type in the human subject result, in the majority of instances, from the ingestion of milk from infected cattle. It is difficult to obtain exact figures as to the incidence of infection in dairy cattle, but approximately 40% react to the tuberculin test and about the same proportion of cattle are found infected on slaughter in abattoirs. That raw milk should suffer as a result is a natural consequence. Thus Brownlie (1933) found that 10% of churn samples of retail milk in urban areas in Scotland contained tubercle bacilli.

Contamination of milk supplies by an organism such as the tubercle bacillus, whose virulence is capable of easy demonstration both in the experimental animal and in the unfortunate human patient, rightly has greater claim to attention than the general cleanliness of the milk, by which term is meant freedom from bacterial contamination, irrespective of the type of organism present. Nevertheless, questions of both economic and public health importance depend upon this latter quality.

The following data were recorded as the result of an investigation into the raw milk supplies of an urban community in which it was estimated that 50% of retailed milk was of this type.

Methods

A sample of milk measuring 300 c.cm. was taken into a sterile container from the raw milk exposed for sale in the retailer's premises on the morning of delivery and brought immediately to the laboratory for examination. Three tests for cleanliness were then applied. Two of these were the plate-count and presumptive *B. coli* tests, recommended in the Milk Special Designations Order, 1936, Scotland. The third test was the methylene-blue reductase test, introduced under the Milk Order, 1936, England and Wales, as a substitute for the plate-count test. In addition, many of the milks were examined for the presence of tubercle bacilli. The methods used are, in brief, as follows:

1. *Plate-count Test.*—Decimal dilutions of milk in 90 c.cm. of diluent were prepared. From the 1/100 and 1/1000 dilutions three separate 1-c.cm. volumes were plated in Wilson's (1935) yeastrel agar medium. After incubation at 37° C. for 48 hours colonies were counted by means of a hand lens and tally counter.

2. *Presumptive B. coli Test.*—Three tubes of MacConkey's fluid medium were each inoculated with 1 c.cm. from the 1/1000 dilution of milk. The presence of acid and gas after 48 hours' incubation at 37° C. was noted.

The standard upon which the quality of samples was judged by the above tests was that demanded of standard milk by the

Scottish Order, 1936—i.e., fewer than 200,000 viable bacteria per c.cm. and no *B. coli* in 0.01 c.cm.

3. *Methylene-blue Reductase Test.*—The modified test described Wilson (1935) was adopted. To 10 c.cm. of milk in a standard sterile test-tube, 1 c.cm. of methylene-blue solution was added. The tube was fitted with a rubber bung, placed in a water bath at 37° C., and inverted at intervals of 30 minutes.

The standard upon which the quality of the milk was judged was that demanded of "accredited milk" under the English Order, 1936—i.e., the milk must not decolorize methylene-blue within 4½ hours if the sample is taken at any time from May 31 to Oct. 31; or within 5½ hours if taken at any time from Nov. 1 to April 30.

4. *Examination for Tubercle Bacilli.*—100 c.cm. of each sample was centrifuged for 30 minutes at 3,000 r.p.m. The resulting deposit was then resuspended in 5 c.cm. of the supernatant fluid, and the entire bulk injected without further treatment into the inguinal region of a guinea-pig. Eight weeks later, if not already dead, the animal was killed. The macroscopic appearances of any tuberculous lesions present were confirmed by the examination of stained films. All animals were kept in separate cages, and in no instance were lesions of tuberculosis noted other than those resulting from the injection of the milk samples.

Results

Examination for Gross Bacterial Contamination.—The completed examinations by all three tests for cleanliness are summarized in Table I. It will be seen that, irrespective of the test used, approximately half the specimens failed to reach the desired standard. The highest proportion of failures—namely 53%—was obtained by means of the presumptive *B. coli* test, which was included as an indication of excretal contamination. Of the 116 specimens examined, 60 were taken during the winter months and 56 in the following summer period. The influence of climatic factors on the condition of the retailed milk is indicated in Table II. Thus during the colder period the percentages of failures in the plate-count, presumptive *B. coli*, and reductase tests were 20, 28, and 30 respectively. In the summer period these figures rose to 76, 78, and 66. The quality of raw milk could not be correlated with the amount handled by individual retailers.

Table I.—*Examination of* 116 *Samples of Retailed Raw Milk by Various Tests for Cleanliness*

Test	Result	
	Passed	Failed
37° C. plate-count	61 (53%)	55 (47%)
Presumptive B. coli	55 (47%)	61 (53%)
Methylene-blue reductase	61 (53%)	55 (47%)

Table II.—*Comparative Results of Tests for Cleanliness in* 60 *Winter and* 56 *Summer Samples of Retailed Raw Milk*

	Winter Samples	Summer Samples
1. Failing 37° C. plate-count test	12 (20%)	43 (76%)
2. ,, presumptive B. coli test ..	17 (28%)	44 (78%)
3. ,, methylene-blue reductase test ..	18 (30%)	37 (66%)

Examination for Tubercle Bacilli.—In all, 93 of the specimens of raw milk were also examined for the presence of tubercle bacilli, and 19 (20%) were found positive. For interest, it may be noted that 5 of the positive specimens passed all three tests for general cleanliness, 11 failed all three tests, while the remaining 4 failed in one or more test. During the investigation 16 retail shops were visited.

Commentary

These results serve to indicate the continued unsatisfactory condition of raw milk supplies. The proportion of retailed milk of this class varies greatly in different centres, but in the larger towns and cities the tendency is towards a gradual reduction. Nevertheless the untreated product is still widely used in rural areas and in smaller townships. As Griffith and Smith (1935) have shown, it is in such areas that the incidence of bovine tuberculosis is highest. Little comment is necessary in regard to the demonstration of tubercle bacilli in one of every five specimens in the series examined, save to mention a popular quasi-scientific criticism that pasteurization, resulting in the destruction of any tubercle bacilli present, may remove the stimulus to an acquired immunity. Apart from the absence of any satisfactory scientific demonstration of this possibility, one may quote Bendixen *et al.* (1937), who ask, in referring to the fact that in 1931 about 2,600 persons died from tuberculosis of bovine origin in Great Britain, "What other method of vaccination would be tolerated that exacted such a sacrifice?"

The gross bacterial contamination found in so many of the specimens beyond the limits recognized for the lowest grade of milk under the Milk Orders, 1936, also requires serious consideration. The question at once arises, To what extent has legislation influenced methods of production and distribution? No doubt much has been accomplished by these means, but there is still room for vast improvement. In fact, it must be considered whether the situation can be met only by the immediate institution of compulsory pasteurization. For a reasoned summary of the possible effect of the adoption of this measure the report by Bendixen *et al.* should be consulted. In this report the advantages of efficient pasteurization are adjudged to outweigh any possible disadvantages. A further criticism has been that pasteurization may result in the loss of certain growth-promoting properties of raw milk. Wilson, Minett, and Carling (1937) in a controlled experimental study found nothing to suggest that, for calves, the nutritive value of holder-pasteurized milk was in any way inferior to that of the raw product.

Conclusions

Of 116 specimens of retailed raw milk, the percentage failing the standard plate-count, presumptive *B. coli*, and methylene-blue reductase tests were 47, 53, and 47 respectively; during the summer months the corresponding percentages rose to 76, 78, and 66, respectively.

20% of these specimens contained virulent tubercle bacilli.

Compulsory pasteurization of milk is considered an essential measure.

Medical Memoranda

Obstructed Labour due to Conjoined Twins

The following case report may be considered interesting enough to warrant publication.

Case History

A primigravida aged 25 was admitted to hospital at 5.15 a.m. on Sept. 8, 1941, as an emergency case. The history was that of a normal pregnancy, with an estimated duration of approximately 38 to 39 weeks. Her general health was good. Onset of labour occurred at 2 p.m. on Sept. 6 with slight pains; spontaneous rupture of the membranes took place at 6 p.m. on the 7th. Two vaginal examinations were made at the patient's home by the midwife, the second one at time of rupture of the membranes. The doctor called in on account of delay in the second stage ordered the patient into hospital with a provisional diagnosis of persistent occipito-posterior position.

On admission to hospital her general condition was good, and the blood pressure 128/84. She was a healthy-looking woman of rather robust build. The uterus corresponded in size to that of a normal full-term single pregnancy. Pains were strong and very frequent, and the caput was well visible during pains. The foetal heart was regular: rate 132 per minute.

Progress after Admission and Manner of Delivery.—In view of the normal size of the uterus and also (apparently) of the head distending the perineum, the possibility of twins was not at first considered. Preparations were immediately made for conducting delivery, which seemed to be about to occur forthwith. One hour after admission, however, the woman was still undelivered, in spite of the fact that the head appeared almost "crowned" during pains. The pains were now very strong, and came on in rapid succession. The foetal heart could be auscultated only with difficulty, but was evidently becoming slower. At this stage the perineum was infiltrated with local anaesthetic and an episiotomy was performed. No further advance resulting from this, Wrigley's short forceps were slipped on and the head delivered (in the occipito-anterior position). The head did not, however, come down fully, and the chin was freed with difficulty. The appearance was as if something were pulling the head back again into the vagina. There was no sign of respiration. By employing head traction and pressure on the fundus the arms were eventually and with great difficulty delivered. The trunk had not advanced during this manœuvre, and, the head and shoulders being born, it was clear that some uncommon cause of obstruction must be present. The uterine contractions by this time were becoming dangerously tetanic, so that a speedy delivery was imperative.

General anaesthesia having been started, a hand was passed into the vagina to determine the cause of the obstruction. Foetal limbs were felt in the region of the pelvic brim, tightly gripped by the lower uterine segment. Amyl nitrate was administered—effecting a slight degree of relaxation—but attempts to deliver the trunk again proved unsuccessful. The thorax was now opened and eviscerated. Exploration being thus rendered less difficult, the presence of twins was established by the discovery of a third arm. A little later it was realized that some kind of double monster must be present, as foetal parts could be palpated without a break in continuity from the arm of the second twin on to the trunk of the first. After this, delivery of what proved to be a double monster of the thoracopagous type was effected in a few seconds. The third arm, mentioned above, was pulled down, and after it the fourth, then all four legs in succession. Traction on the legs brought out the buttocks, and lastly came the trunk, shoulders, and head of the second half of the monster.

The third stage was completed in a normal manner. The uterus was well contracted afterwards, and the general condition of the mother was good. The puerperium was quite normal, and the patient was discharged home on the 12th day.

The Specimen.—The two halves of the thoracopagus were approximately equal in size, each having a normally developed head and limbs (see accompanying photographs). They were joined face to face, by soft tissues only, down the front of chest and upper abdomen. The placenta was single, and there was a large common exomphalos, into which ran the single umbilical cord and inside which coils of intestine were visible. The monster weighed 8 lb. 7 oz., and the length of each half was approximately 19 in.

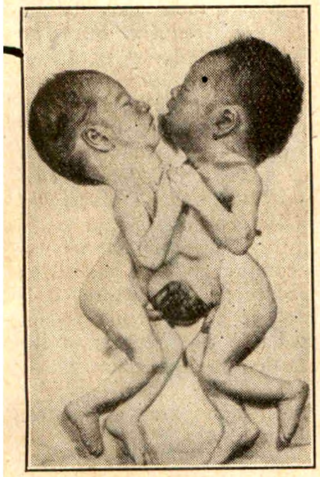

FIG. 1

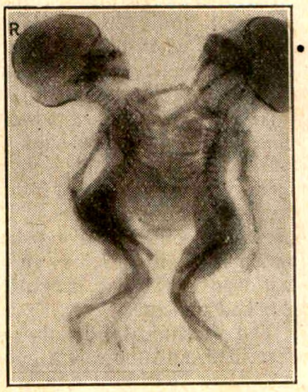

FIG. 2

COMMENTARY

Delivery was not difficult after crushing of the thorax of the first twin had allowed adequate access for exploration and diagnosis. Had the monster been larger it would doubtless have needed dividing into its two halves to make delivery possible. The ventral connecting portion, being of soft tissues only, was lax enough to permit some movement of one twin relative to the other. At one point during the manipulations the two heads were stretched out so as to constitute the opposite extremities of the monster, with the two trunks and all the limbs between them.

In this connexion the following description from Whitridge Williams's *Obstetrics* may be quoted: "Thoracopagi are frequently so loosely connected with one another that considerable motility is possible. Indeed, it is not unusual for the two children to present in a different manner. When possible, it is advisable to bring down all four feet at the same time and to effect extraction in such a way that the posterior head is first delivered. In cephalic presentations the head and body of the first child is expelled and the second child is then born very much as in an ordinary twin pregnancy. If, however, the latter presents transversely, its delivery can be effected only by version and extraction."

I am indebted to Dr. James Clark, medical superintendent, and Dr. W. J. Clancy, senior obstetrician, for permission to publish this case.

EDWARD RIDEHALGH, B.Sc., M.B., Ch.B.

City General Hospital,
Sheffield.

A Case of Polyradiculoneuritis

The following case seems to be interesting enough to merit publication.

CASE REPORT

The patient, a ham-curer aged 50, was admitted to the Victoria Infirmary, Glasgow, on Sept. 1, 1941, suffering from symptoms of polyneuritis which conformed very closely to the syndrome first described by Guillain, Barré, and Strohl (1916). The symptoms also closely resembled those described by H. Stuart Barber (1940).

For some weeks before the onset of paralysis he had felt pain in the lumbar region. This was not very severe but was constant, and his doctor had given him some medicine for it. For a few days previous to the paralysis his urine was highly coloured; he described it as being "red." On Aug. 25 he had gone to work and had done his job as usual. The next morning he could not stand. He had no other complaints, apart from the slight pain in his back. He became very restless during that day, and did not sleep on the following night, an irritation of the skin causing him to scratch himself to the point of drawing blood. On Aug. 27 he had palsy of the left side of the face and some twitching of the muscles of the right side of the face.

On admission there was double facial palsy, with inability to close his eyes, definite muscular weakness of both arms, and complete paralysis of both legs. The biceps and triceps reflexes were weak. Abdominal reflexes, knee-jerks, and ankle-jerks were absent. There was no loss of sensation either to superficial or deep tactile stimuli or to pain. Pronounced nuchal rigidity and Kernig's sign were present. Sleeplessness was a marked feature of the acute stage of his illness, but headache was not complained of. The temperature was normal; there was some tachycardia, the pulse rate being about 100 during his first week in hospital, later falling to 80. The urine was normal and contained no blood. Lumbar puncture revealed a normal fluid pressure. The cell count was 4 per c.mm.; protein, 122 mg. per 100 ml.; chlorides, 733 mg. NaCl per 100 ml.; sugar, 84 mg. per 100 ml. The blood leucocyte count was 19,300 per c.mm.; the sedimentation rate was not estimated; the Wassermann reaction was negative.

Dr. Conway, ophthalmic surgeon to the hospital, reported on Sept. 4 that the edges of the left optic disk were blurred, but that the condition was short of true swelling of the disk. The right optic disk was well defined but showed definite nasal pallor. There was no paralysis of the external muscles of the eye.

The patient's condition became worse for a few days after admission, and he was incontinent of urine on several occasions. After a week improvement was noticed and he was able to move the legs slightly. The improvement continued without interruption, and eight weeks after the onset recovery was almost complete, except for slight paresis on the left side of the face, and he was able to walk with assistance. The knee-jerks and ankle-jerks were still absent.

Comment.—The features of this case are: the sudden onset of paralysis affecting the legs, arms, and facial muscles, distribution being symmetrical; the comparatively rapid and complete recovery; the normal temperature throughout; the tachycardia; and the cerebrospinal fluid under normal pressure, with normal cell count but high protein content. These features are so similar to those described by H. Stuart Barber and others as to suggest that a specific virus might be the cause of this condition.

ALEX. GLEN, M.D.,
Visiting Physician, Victoria Infirmary, Glasgow.

Reviews

PSYCHOTHERAPY

The Therapy of the Neuroses and Psychoses. By Samuel Henry Kraines, M.D. (Pp. 512. 25s.) London: Henry Kimpton. 1941.

This book has the merit of concentrating on what most books tend to put into a secondary place—namely, treatment—and for this reason it should appeal especially to the practitioner and the student. The accounts of treatment with which it is mainly concerned are such as might, with a reasonable amount of time at his disposal, be used by the family doctor. The author's chief methods might even be described as those of common sense.

For a variety of reasons psychotherapy has tended to depart in recent years from the obvious. Much has been hoped for from psycho-analytic methods, and a good deal if not all that has been hoped has been fulfilled. To the uninitiated there is a promise in psycho-analytic methods of something like magic in the removal of symptoms by a performance akin to a surgical operation, with the minimum onus on the patient, and perhaps not demanding much more of the doctor than a capacity for sustained attention and some intellectual dexterity. They have the appearance of taking responsibility away from the patient and leaving the cure to the efforts of the doctor, or at any rate to Nature, with the doctor acting as a kind of psychological midwife. But the unique success of the Freudian method in certain cases, as well as the vast panorama of psycho-analytic observation and theory generally, has caused the influence of factors other than complexes and the like in producing breakdown to go out of fashion. The effects of pernicious upbringing, of misguided types of education for life, and of the accumulation of faulty habits are unsensational, but they are probably more often the cause of psychoneurotic illness than is nowadays suspected.

Dr. Kraines undertakes the task of treating his patients from this point of view, and seeks to retrain them in their habits and attitudes by teaching them to observe themselves, to control their more selfish or more primitive impulses, to adopt a rational rather than an emotional attitude, and to reorganize their lives in the light of an analysis of their character and behaviour. Conscious rather than unconscious factors are stressed throughout, although there is a purely descriptive chapter on Freudian theory appearing rather uneasily at the end of the book. Emphasis is laid on the need for control rather than on emancipation through recapitulation and catharsis. It is true that some of the advice seems very obvious, almost distressingly so in the section headed. "Therapy of Stress by Removal: Financial Assistance the Best Therapy, especially in the Case of Actual Want." How often has even the novice had this glimpse!

LEUKAEMIA IN ANIMALS

Spontaneous and Experimental Leukaemia in Animals. By Julius Engelbreth-Holm, M.D. (Pp. 245; illustrated. 15s.) Edinburgh and London: Oliver and Boyd. 1942.

The monograph on *Spontaneous and Experimental Leukaemia in Animals* by Engelbreth-Holm has been written at the request of the scientific advisory committee of the Lady Tata Memorial Trust and is published under the Trust's authority. The translator and the scientific committee are to be congratulated on the lucid style of the English, while the Trust and the publishers are to be congratulated on the production of so well-printed and well-illustrated a book at so reasonable a price. Its appearance at the present time is peculiarly appropriate because in more senses than one it marks the end of a period. It summarizes research which had gained a fresh impetus since the inception of the Trust's work in 1932, and it is characteristic of the truly international outlook of the Trustees that the book should have been written by a Dane and produced in England with the support of a Trust founded by an Indian. That international outlook is for the moment obscured, but when it clears again this monograph will serve as an indispensable guide for the resumption of research on the leukaemias. It describes the occurrence and morbid appearances of leukaemia in a great number of birds and mammals. It is not generally known that leukaemia occurs with sufficient frequency in fowls and cattle to constitute at times a serious economic problem. Transmission experiments have shown that certain varieties of fowl leukaemia can be transmitted by a virus, and there is suggestive evidence that one and the same virus may under different conditions produce leukaemia or sarcoma. In mammals leukaemia can be transmitted only by transplantation of cells, but in the mouse pure strains can be bred in which the incidence of spontaneous leukaemia is 90%. Leukaemia may also be initiated by carcinogenic agents. Thus the same factors are of importance in leukaemia as in neoplasia—virus, heredity, and chronic irritation. It is probable that research on leukaemia would have taken a more chemical trend under the stimulus of recent work on the chemistry of the viruses and the genes. For this we may now have to wait till after the war, but veterinarians, haematologists, and experimental pathologists will be permanently indebted to Engelbreth-Holm for his able record of the progress to date.

TREATMENT OF SHOCK

The Treatment of Shock. By R. W. Raven, Major, R.A.M.C. Oxford War Manuals. (Pp. 96. 5s.) London: Oxford University Press. 1942.

Shock in its various forms is a central problem of war medicine and surgery. The intense interest of practical surgeons and the zealous investigations of research workers in all branches of medical science have done much to advance our knowledge of this complex subject, both in the last and in the present war. It is eminently desirable that accurate and up-to-date information be made readily available to medical men serving on our various war fronts. Had this manual fulfilled these requirements it was assured of a warm welcome. Unfortunately these hopes are disappointed.

Following a satisfactory introductory chapter in which Blalock's excellent classification of shock into neurogenic, haematogenic, vasogenic, and cardiogenic is quoted, the author lapses into the old unsatisfactory subdivision of primary and secondary varieties. The clinical description of shock is poor —e.g., the mental state is described as follows (p. 14): "There is apathy, stupor, delirium, and unconsciousness." Many incomprehensible statements occur such as, "Excessive preoperative medication, especially in aged patients, may precipitate a condition of shock from which there may be no recovery" (p. 8). Misstatements are frequent even on important and crucial matters. To say that losses of 4.5 or 5.1% of the total blood volume cause death (p. 20) is obviously incorrect, and even Keith's finding that the patient's condition was grave when blood volume was reduced to 85% (p. 22) has been completely upset by recent work: Wallace and Schafer showed that blood loss in man of 1,200 c.cm. (25% of the total blood volume) was well tolerated. Brennan's claim that plasma transfusion washes side-tracked corpuscles into circulation again is accepted uncritically. The section on oxygen therapy is confused by failure to comprehend the underlying physiological principles. Haemoconcentration, which only occurs in burns and crush injuries, is given undue prominence in discussion. Even the available case reports of the last war show that haemoconcentration rarely occurs in the shocked patient.

The technical details of transfusion are adequately described, and there is a good bibliography.

BORSTAL THROUGH AMERICAN EYES

Criminal Youth and the Borstal System. By William Healy, M.D., and Benedict S. Alper. (Pp. 251. 8s. 6d. net.) New York: The Commonwealth Fund; London: Oxford University Press. 1941.

It takes a foreigner to appreciate our institutions to the full, and one of the best existing books on the Borstal system has now been written by two Americans, both with long experience of practical criminology. It seems that the methods used in the United States for dealing with youthful offenders leave a good deal to be desired. Although in theory reformatory treatment is provided for younger criminals, American reformatories are only prisons under another name, and the system has shown no appreciable success. Dr. Healy was convinced of the value of the Borstal system by an observation of it which he made in 1929. In 1938 he made a second study for the American Law Institute, and the war cut short a third intensive study financed by Mr. J. D. Rockefeller, in which Mr. Alper took part. The authors are therefore well qualified to write on the work of the Borstal institutions. They trace the history of the system from its inception in a wing of Bedford Prison, through its establishment as a recognized part of the penal system after the passing of the Prevention of Crime Act in 1908, to the latest developments, a few years before the war, of North Sea Camp and Prescoed. They summarize the law and practice which govern committal to Borstal, and the system of allocation, and they go on to describe the general principles of the training, and especially its flexibility, so that the length of time each offender shall spend in an institution and that which he shall spend on licence to the Borstal Association are made to correspond with his individual requirements.

The house system, the steady balanced life, and the personal relationship, with the other essentials of this valuable discipline, are appreciated in detail. A chapter describes the recruitment of the staff from men of very varied types, having in common initiative, strength of character, and experience of life. Staff-inmate relationships, the training programme, and home and community relationships are studied in equally precise detail, and the special features of the different institutions are described. The authors' remarks on weaknesses in the system are worth special attention, and the first which they indicate is the absence of any consistent attempt to apply psychological knowledge to the treatment of abnormal personalities. They also criticize gravely the existence of a legal maximum period of four years after which an offender may not be held. While they do not advocate a completely indeterminate sentence, they agree with those governors who would have, for some youths, a longer time in an institution and a much longer time on parole. Their final chapter on the possible application of the system to American needs is rather for their own countrymen, but their masterly analysis will greatly assist English penologists and, no doubt, reformers in other countries.

Notes on Books

Prof. A. **MUIR CRAWFORD** of Glasgow has now produced a fifth edition of his little book *Materia Medica for Nurses* (H. K. Lewis, 4s. 6d.). Many changes have been made in the text, and the scope of the work has been enlarged to include descriptions of some of the newer drugs. There are additional chapters—one on the sulphonamide group and one on the Dangerous Drugs Acts and the Pharmacy and Poisons Act.

An illustrated pamphlet entitled *Some Emergency Anti-Malarial Measures*, by Sir **MALCOLM WATSON**, director of the Ross Institute of Tropical Hygiene, has been issued by its industrial advisory committee. Copies may be obtained on application to the organizing secretary of the Ross Institute, Keppel Street, London, W.C.1.

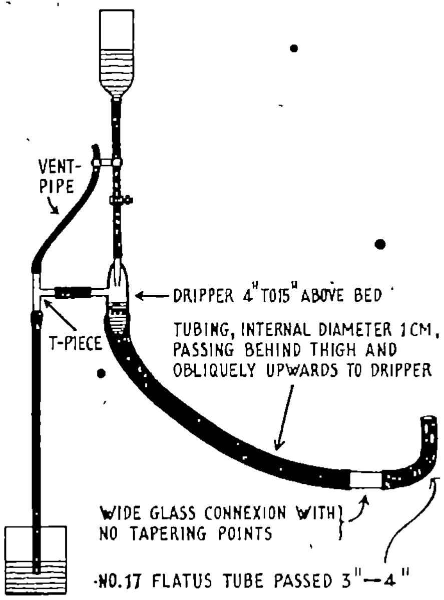
Preparations and Appliances

RECTAL ADMINISTRATION OF FLUID

Mr. D. C. **CORRY**, M.D., F.R.C.S., Surgeon to the Radcliffe Infirmary, Oxford, writes:

After the mouth the rectum is the most physiological route for giving fluid. J. B. Murphy (1909) was the great advocate of this method, and reported that he very often gave 15 pints of fluid a day by this route. The points he stressed were: (1) that the tube in the rectum must be large enough for flatus to be passed; (2) that the column of fluid must not be higher than 4 to 15 inches; (3) that the tube to the reservoir must have an internal diameter of at least 3/8 in. (1 cm.); (4) that the fluid be given intermittently. He achieved this originally by a flat pan reservoir, and into this flatus and faeces were regurgitated.

For the last year I have been giving rectal fluids, using the same principles but utilizing a dripper with a side arm. By this method 2 to 8 pints can be given in 24 hours. Even if the patient takes only 2 pints this is a useful addition to his body fluids, and is an improvement on the cases we used to meet of which we were told, "He will not retain any rectal fluids." The side arm on the dripper allows flatus and fluid to escape, so that the patient is comfortable with the tube in the rectum. A glass T-piece is attached with one branch going upwards. This serves two purposes: it prevents a siphon effect from developing when the fluid from the dripper escapes out of the side arm, and acts as a vent-pipe for the flatus. A foot of rubber tubing is fitted to this upper limb of the T-piece and is strapped to the adjacent tube. This prevents the ejection of faecal fluid from the top of the tube. The lower end of the T-piece goes into a receiver. A flatus-tube (No. 17 English catheter gauge) with end and side openings is used in the rectum. This is joined by a wide-bore glass connexion with 2 ft. 6 in. of wide-bore tubing the internal diameter of which is 1 cm. This is connected to the dripper, which must not have too tapering a lower end. With a wide-bore tube and wide-bore connexion, flatus can escape freely back and the patient is comfortable. The height of the dripper above the bed is 10 in. It may be necessary to increase the height to 15 in. For acute appendicitis, when it is thought desirable to give fluid, I limit the height to 8 in. out of respect for the appendix stump. Before inserting the flatus-tube, fill the tubing below the dripper with fluid and then pass the flatus-tube below the thigh and 3 in. to 4 in. into the rectum. Strap the flatus-tube to both buttocks.



VENT-PIPE
DRIPPER 4" TO 15" ABOVE BED
T-PIECE
TUBING, INTERNAL DIAMETER 1 CM, PASSING BEHIND THIGH AND OBLIQUELY UPWARDS TO DRIPPER
WIDE GLASS CONNEXION WITH NO TAPERING POINTS
NO. 17 FLATUS TUBE PASSED 3"—4"

For rectal drip, usually tap-water and 5% glucose is used as a routine post-operatively in any major case. I normally limit the fluid intake to 6 pints a day. On return from the theatre, while semi-conscious, the patient will tolerate rectal fluid given by any method better than when conscious. The drip is therefore started at a rate of 80 drips a minute (half a pint an hour) and slowed down to 40 drips after two hours. When the apparatus works unsatisfactorily it is usually due to air-locking, which may occur in spite of the tube to the dripper being 1 cm. in diameter. Pressing the tube where it passes under the thigh may expel the bubble. If this fails, take out the rectal tube, allow fluid to run through till the tube fills, and re-insert.

Apart from abdominal cases, it is useful in genito-urinary cases, especially after prostatectomy, in which it is desirable to keep the kidneys functioning adequately. In subtotal thyroidectomies it may help to lessen thyroid crises, as glucose and water are sometimes employed to treat these crises when they occur. It certainly helps to make these patients comfortable after thyroidectomy, saving the trouble of reaching out for frequent small drinks, which on account of the neck operation are painful to swallow.

In addition to making the patient so much more comfortable and fit the next day, I consider it is possible that by the use of the rectal drip (plus sulphanilamide in infected cases) the incidence of pulmonary embolism may be lessened

I wish to thank my house-surgeon, Mr. Peter Henderson, and Sister T. M. King for their help in the application of the apparatus.

SATURDAY JULY 4 1942

DOES HEALTH EDUCATION HELP?

Never perhaps has this country become so conscious of its health as in the months that have passed since September, 1939. A sick person means an inactive person, and the output of work of a man whose health is below par falls below that of which he is fully capable. After the fall of France we were brought face to face with the fact that this country was small and, compared with Germany and her satellites, numerically inferior in population. Each man and woman counted, and numerous agencies were set to work to keep the health of the country at as high a level as possible. In this the Ministry of Food has come out with flying colours, and its imaginative as well as its realistic handling of an activity that is more important than any other in maintaining and promoting health will, when the balance sheet comes to be added up after the war is over, be found to be very much to its credit. Food propaganda—instruction in food values and in cooking—is one aspect of health education. And the success of this is partly an answer to those who doubt the value of such education. Dr. Donald B. Armstrong, Vice-President of the Metropolitan Life Assurance Company of New York, observes[1] that in the U.S.A. "there are still those in public health who see little or no value or scope in health education." And what is true of the U.S.A. is probably true here. It is indeed a matter in which it is easy to lose perspective, and to attribute to health teaching, say, the decrease in droplet infection and the increase in immunization against diphtheria, and the decrease in respiratory tuberculosis to the control of arbitrary spitting.

Those who believe in the value of health education have been encouraged by the experience of the Metropolitan Life Assurance Company of New York, and it is this which makes Dr. Armstrong's observations of particular interest and value. His company has for years carried out an extensive health programme among its industrial policy-holders. It has employed every medium of propaganda, and those in this country who see the American weekly magazine *Time* have probably noticed with interest the advertisements of the Metropolitan Company in relation to health matters. The company has, of course, been able to follow up its general programme with the special educational efforts of its agents, who come into contact with the individual person in the home. That a large business concern should undertake such a wide measure of public health education is an interesting commentary on the times in which we live. The company itself would probably be the last to claim that it did this work from philanthropic motives or from the reaction of an acute social conscience. It started, and has continued, the work because it pays. Since 1911 the policy-holder group is estimated to have gained about 17 years in life expectation, as compared with about 10 years for the country's population in general. It has been calculated that in 1939 alone the lives saved were approximately 112,000 in excess of those that would have been saved if the policy-holders had experienced only the benefits shared by the general population of the country since 1911. Closer analysis shows that since 1911 there has been a 92% improvement in diphtheria mortality among the general population of the U.S.A., and a 95% improvement in the industrial-policy-holder group—a 3% gain. In pneumonia there has been a 7% gain, in tuberculosis a 10% gain, in puerperal diseases a 17% gain.

Both groups have shared the influences that have led to the general improvement in health. The insured group has been subjected to an intensive health education campaign. The matter is slightly complicated among this group by the facts that the Metropolitan Life Assurance Company provides a nursing service for its acutely ill policy-holders, and that in this nursing service special attention has been paid to diseases of the puerperal state and to communicable diseases such as diphtheria and pneumonia. So in attributing to health education any improvement in health and expectation of life among policy-holders this nursing factor is one that must obviously be taken into account. Dr. Armstrong believes that a more sensitive index of the value of health propaganda is afforded by the attack his company made upon the problem of appendicitis in 1934. The campaign was aimed at preventing unnecessary fatalities from this disease, and was carried out by means of pamphlets and articles, advertisements, posters, lectures, and news releases. During this period appendicitis mortality improved by more than 30%. This coincided with an improvement of 24% in the general population. During this period there were no important advances in the diagnosis or treatment of appendicitis, with the one exception of the quite recent use of sulphonamide drugs in the treatment of peritonitis resulting from perforation. It would, in fact, seem reasonable to attribute the improvement obtained to health education.

But Dr. Armstrong, from his wide and unique experience, utters what is in effect a warning to health educators—namely, that they should not take themselves too seriously. At the moment attention is being focused on the results of examining large numbers of entrants to the fighting Forces in the U.S.A., and enthusiastic health educators are anxiously wondering whether the results will reflect upon the efficiency of the teaching for which they have been responsible. Dr. Armstrong suggests that health education is not the only or the most important factor in any rise or fall in the rejection of recruits. In the first place the experience of the last war and the advances in medicine made since have led to an altered conception of what we mean by fitness and of the medical standards of entry into the Services. Then again, there have been big advances in diagnostic equipment, in hospital services, in treatment, in knowledge of normal standards of nutrition, and changes in such fundamental matters as standards of housing and living. Health instruction for the public at large has not been without effect upon the doctor himself. Dr. Armstrong in fact states unequivocally that some doctors first heard of the Schick test through "lay contacts or through the perusal of literature primarily intended for lay consumption." Some efforts have, in his view, been misdirected, and he cites the fanatical outburst of tooth-brushing that went on 20 years ago, when "whole schools and squads of children were mobilized in playgrounds and elsewhere and exposed to toothbrush drills, thus over-emphasizing this already exaggerated point." Parenthetically he observes that if the time and money that had been spent on this one aspect of health teaching had been devoted, for example, to research on the relation of dental caries to nutrition or to heredity, something more constructive might have emerged. Since then the toothbrush has been blamed for injuring gums and eroding teeth, and health educators perhaps had better be warned now not to swing over in the opposite direction of recommending no toothbrush at all.

---

[1] *J. Amer. med. Ass.*, 1941, 117, 2060.

As a further corrective to an unbalanced attitude towards the virtues of health education, Dr. Armstrong describes the experience of Canada and the U.S.A. last year, when an "influenzal pneumonia outbreak" spread across those two countries from west to east. In most parts of both countries, in spite of an increase of influenza and its accompanying pneumonia, the death rate from the latter as compared with 1940 actually fell, but in Quebec there was a sharp rise in the mortality from pneumonia; this, he believes, was due to the fact that medical practice and public health procedures are backward there in comparison with other areas. The interesting point is that the Metropolitan Life Assurance Company insures a larger percentage of the population in Quebec Province than elsewhere, and it has there also concentrated on health teaching to the extent even of "preparing health education material in the native language." In an attempt to find the significance of health education in relation to the numerous medical, nursing, public health, and sanitary agencies, Dr. Armstrong likens it to an enzyme the function of which is to accelerate changes in a certain direction.

We believe that on the whole this country has been backward in enlightening the public in health matters, and also that in the future such teaching should play an important part in the new Britain which reformers do not altogether despair of seeing. But those who enter into this work must get the part they play in it into the right perspective. It is, for example, no good recommending what a well-known Hyde Park orator used to recommend every Sunday to an admiring audience—namely, duck and green peas three times a day—(1) if these delightful commodities are not available, (2) if people have not the money to buy them, and (3) if in practice one can have too much of a good thing. The health educator, in fact, must always be aware of the limits imposed on his work by social factors beyond his immediate control. His efforts may, too, be hindered by inefficient or inadequate medical services, or by a medical profession apathetic because of an educational system that still lays too great stress on the end-products of disease—morbid anatomy and morbid histology. But given every desideratum, there still remains one pernicious influence which will always work against health education, and that is the morbid interest in disease which is kept alive and inflamed by the advertisements of patent medicines.

FURTHER LIGHT ON HYPERTENSION

Goldblatt and his co-workers[1] showed that in experimental animals the artificial production of renal ischaemia by constriction of the renal arteries led to persistent hypertension. If the constriction was severe enough there was a clinical picture of malignant hypertension, and widespread pathological changes were found in the arterioles. The kidneys themselves, however, escaped this change, as they were the only organs in which the effects of the hypertension were not felt owing to the experimental conditions under which it was brought about. Wilson and Byrom[2] followed up Goldblatt's work and showed that in some animals, especially the rat, severe malignant hypertension could be produced by constriction of the renal artery on one side only, and in such cases the pathological changes were found not only throughout the body, but also in the kidney the blood supply of which had not been reduced. In some further work these same authors[3] describe the "vicious circle" in chronic Bright's disease—that is, hypertension caused by renal ischaemia leads to further changes in the blood vessels of the kidney itself; which in turn increase the ischaemia and therefore the degree of hypertension. When one renal artery is partially occluded by a clamp and hypertension thus brought about, removal of the clamped kidney causes a return of the blood pressure to normal in a proportion of the cases only. Where the hypertension has persisted after removal of the clamped kidney, vascular changes have always been found in the opposite kidney. Finally, evidence shows that the residual hypertension may itself give rise to further lesions in the remaining kidney, and so progressive renal destruction takes place.

The clinical implication of these experiments is that malignant hypertension in man may be looked upon as a syndrome which may result from any pathological condition of the kidney giving rise to ischaemia. This explains why in patients suffering from benign hypertension, chronic nephritis, or chronic pyelonephritis there may be a sudden aggravation of their hypertensive state with retinal changes and deterioration of renal efficiency. The same malignant termination may be seen in cases starting as toxaemia of pregnancy or as lead poisoning. This conception also explains the histological finding of acute fibrinoid necroses of arterioles and glomeruli superimposed upon a variety of more chronic renal lesions. Malignant hypertension with typical renal changes may also occur as a terminal stage in pituitary basophilism, in which the primary hypertension is probably not of renal origin at all.

A number of cases have now been recorded in which unilateral renal disease has been the cause of hypertension in the human subject. In some of these the hypertension disappeared when the faulty kidney was removed; but in others secondary vascular damage in the opposite kidney had already occurred and residual hypertension remained. In view of the experimental work of Wilson and Byrom it is important in such cases that the damaged or functionless kidney should be removed as early as possible. Derow and Altschule,[4] who come to the same conclusion about malignant hypertension as Wilson and Byrom, consider that the pathologists who in the past have thought it to be a specific disease have been misled by grouping together pathologically identical cases and finding that their clinical histories were similar. A more accurate characterization of malignant hypertension is obtained by the opposite process of examining the varied pathology of cases clinically identical in their final stages. These authors set out the conditions in which malignant hypertension has been known to occur, and include in their list essential hypertension, secondary hypertension due to renal disease of various types, and hypertension secondary to endocrine disease and to lead poisoning.

Whether primary essential hypertension is always, or even usually, due to ischaemia of the kidneys in the first place is by no means certain. It is an attractive hypothesis in view of Goldblatt's work and of the fact that in the majority of cases renal arterial changes can be found; but Raab,[5] in a recent article on the origin of essential hypertension, recalls the experimental studies which show that hypertension can be produced also by artificial impairment of the cerebral blood supply, especially if the arterioles to the vasomotor centres are affected. He also gives clinical evidence that this may be the cause of many cases of hypertension in man, and concludes that the problem is not a simple one, and that in most cases three factors—hormonal, central, and renal—are probably operating.

SURGERY IN LIBYA

In dispatches from correspondents in Libya fitting mention has been made of the gallantry displayed by the different units of the armed Forces, but only rarely does one read of the part played by the medical services, which, in a campaign such as the recent disastrous one, must have been taxed to the utmost. In preparations for the fighting in the desert the D.M.S., Middle East, had obtained extra transport so that the light sections of certain C.C.S.s should be independently mobile, and the heavy sections at least more mobile than they had been in the past. Mobile operating theatres, each consisting of a sterilizer and an operating van, have proved suitable to desert conditions and "a great boon." In the offensive which began in November last year it was not found possible to keep in constant touch with the surgeon, and the difficulties of travel for ambulance cars was, to say the least of it, considerable. Many of the surgeons in the battle zone were under fire, and some even worked in captivity for varying periods of time. In Libya, we are informed, "the enemy appears to respect the Red Cross so long as it does not conflict with his interpretation of the needs of the tactical situation."

There were certain obvious difficulties in the working of the forward surgical service. Delay in communications led to loss of touch between headquarters and the various units. Transport was not always available when it was wanted, and rationing of water made sterilization and the washing of towels difficult. Lighting was another problem, some surgeons having to work in their operating tents with the aid of hurricane lamps. A familiar complaint is heard in the observation that records were bad and that "surgeons will not write legibly and print their names." Evacuation by air was a feature of the winter campaign, and over a thousand seriously wounded cases were comfortably transported by air from the battle zone either to forward aerodromes or to the base. Among the special centres there were five orthopaedic, two maxillo-facial, two neurosurgical, and two chest units with the Forces. There was apparently some opposition to the transfer of cases to special centres, but no doubt remains that the standard of treatment at them is very much better than at a general hospital. Cases not evacuated by air have taken as long as eight days or more to reach the base hospitals, and in spite of the increased mobility of the surgical units it took most of the wounded twenty-four hours or longer before they came under the care of a surgeon. But, in spite of these and other handicaps, results appear to have been highly satisfactory. By December 29, 1941, for example, there had been no case of tetanus.

Some observations from the base are of interest. "If," we are told, "the forward surgeons could see the big difference in the state of the excised wound as compared with that which had only sulphanilamide powder and dressing, they would realize how much the recovery time is shortened." Again there is a certain amount of complaint about record-keeping. For example, in several cases in which the wound had been enclosed in plaster, no mention was made either on the plaster itself or on the card whether the wound had been operated on or whether a tube had been put in. The dosage and times of administration of sulphonamide were not always stated. There was a high proportion of wounds of the lower limb, and a high proportion in which wounds were complicated by fracture. Many wounds were operated on in the forward area, débridement was carried out, the wounds were "saucerized," sulphanilamide was dusted on the surface, and the wounds covered with a vaseline dressing or loose pack. Cases treated in this way do "extremely well." With the exception of a very few cases, wounds which had been sutured were badly septic on arrival at the base, the sutures cutting out and the patient being in pain from suppuration under tension. It was observed that drainage tubes have been found put in "out of sight in the depths of wounds." Rubber tubes or tissue were found useless for drainage of wounds with established infection. When devitalized and infected muscle was excised, the wound was dusted with sulphanilamide, and a vaseline gauze pack provided drainage, the general condition of the patient improved and the infection did not spread. Another observation is that early amputation of a mangled limb was not only well tolerated but produced "a dramatic improvement in the general condition." Some points made about amputation were that the stumps were sutured far too often, and that cases in which complete skin closure had been done arrived at the base with the sutures cutting out and the skin sloughing. It is stressed that amputation under battle conditions should be planned to permit re-amputation at one of the sites of election, and that when possible some flap should be cut and allowed to fall over the end of the stump. A few loose sutures could be tied over a loose dressing after the stump has been dusted with sulphanilamide, and it is considered inadvisable to apply a plaster cover over the stump at a forward operation centre.

From experience at the special centres it appears that patients with uninfected haemothorax arrived in excellent condition, and that the condition of patients with open pneumothorax improved once closed drainage was established. It would be highly advantageous if some form of closed drainage during transport could be devised. The importance of the proper treatment of wounds is again emphasized by experience of workers at the head centres. Those wounds which healed by first intention had been "thoroughly treated by excision and wound toilet," and it is believed that if other cases which were badly infected had been so treated the incidence of infection would have been less. A brief report of a case in which a brain injury had been packed, followed by cerebral abscess and death, is accompanied by the injunction, "Head wounds should never be packed."

Two types of fracture of special interest are recorded. The first is compression fracture of the spine, which occurred largely in Naval ratings, who sustained the fracture by hitting their heels against the bilge rail when sliding down the side of a sinking ship. Compression fracture of a lower dorsal vertebra was also found in men swimming too near a depth charge, which blew them into the air. The second type is fracture of the os calcis, which occurred, for example, in men standing on the upper deck and receiving a severe impulse from below as the result of a bomb exploding between decks. This type of fracture has been severe, often bilateral, and sometimes compound.

DOCTORS AS POLITICIANS AND STRATEGISTS

If a group of Army officers, or even the 1922 Committee, were to come forward as advocates of the immunization of children against whooping-cough, the medical profession, whatever its opinion of the merits of the advocacy, would wonder with what authority and on the basis of what knowledge such groups of laymen might be presumed to act. The world would be a livelier place if associations of men expert in one branch of knowledge were every now and then to tell other associations how to manage their affairs. The Beekeepers' Association might like to be told how to look after their bees by, say, a group of Conservative engineers whose political views might impel them, for example, to protest against the premature extinction of queen bees. Just as good as these hypothetical examples is the actual and recent resolution of the Socialist Medical Association, passed unanimously, "indicating its desire for the immediate formation of a second front," and a further pronouncement that this body "would urge that steps be taken to give effect to this policy without any dangerous delay." Such ineptitude can perhaps be excused on the ground of naivety, but one would have thought that medical men had enough to do now in their own professional work and in matters concerning the organization of their profession, without wasting time in passing resolutions on matters about which they are neither more nor less informed than any other reader of the daily newspapers. Even in the matter of the supply of medical personnel and equipment for an expeditionary force, we doubt whether the Socialist Medical Association has any information that is not available to the man in the street. If, however, they are speaking not as doctors but as politicians, and as Socialists feel bound to echo a cry that might be supposed to be welcomed by Moscow, then surely the grim realists who are courageously directing Russian policy must, if they have the time to spare, feel mildly amused at the picture of the English doctor turned strategist.

Let us hope that the example of the no doubt earnest men who form the Socialist Medical Association will not be followed by other doctors who hold other political beliefs. The public, we fear, would lose faith in the doctor's good sense if, say, a Liberal Medical Association, a Conservative Medical Association, a Social Credit Medical Association, perhaps a Fascist Medical Association—or even an Independent Medical Association—followed the lead of their prototype by offering gratuitous advice to the Government of the day on extramedical matters. Apart from the slightly ridiculous aspect of such sectional organizations ranged on lines of party politics, we believe that they do a disservice to medicine by weakening the influence of the doctor in public affairs.

A PURE PROTEIN FROM THE POSTERIOR PITUITARY

Whereas the constitution of other hormones has been investigated with some success, that of the hormones of the posterior pituitary remains shrouded in mystery. Indeed, for many years it has been a matter of controversy whether the active principles were separate entities or represented different manifestations of the action of a single substance. In 1919 Dudley first achieved a partial separation of the vasopressor and oxytocic fractions. His observations were confirmed and extended by later workers, who, by using more drastic methods, achieved almost complete separation of the two fractions, though the commercial samples still lag behind somewhat in this respect. However, when reliable methods of assay were devised, it was found that in crude extracts the proportion of, for instance, vasopressor to oxytocic activity was approximately constant for any given species. This led naturally to the suggestion that while it might be possible to separate the active principles artificially, yet they existed in the first place as single components of a large molecule.

The work of van Dyke and his colleagues[1] has now furnished direct evidence of this hypothesis. They have extracted from the posterior lobes of frozen ox pituitaries a protein which contains all the active fractions and which they claim is pure, so far as their physico-chemical investigations allow. Its purity was demonstrated by its constant solubility, and by examination in the ultra-centrifuge and in the Tiselius electrophoresis apparatus. These methods and elementary chemical analysis agreed in giving the protein a molecular weight of about 30,000, and the active principles were present in about the same proportions as they are in crude extracts. This protein is by no means the most potent substance yet isolated. Thus, while 61 microgrammes of solid are equivalent to one U.S.P. unit, previous workers have already isolated an oxytocic fraction said to be thirty times more potent. The prosthetic groups which constitute the active principles must therefore be far smaller and simpler than the parent molecule, a fact which makes their ultimate chemical identification more hopeful.

It might be suggested that these observations could be explained by the adsorption of the active principles by some indifferent medium. The experimental evidence renders this very improbable. But though we may therefore visualize a single molecule which comprises all the active principles, it seems unlikely that it is released into the blood stream as such, though there is as yet no direct evidence either way. So this discovery must lead to speculation on the purpose of the association of vasopressor, oxytocic, and antidiuretic activities in the same molecule. Is it just chance that these three hormones are linked together in the posterior pituitary, for storage purposes perhaps? Or has the association some deeper significance which we have yet to learn?

GRAMICIDIN

Readers of this *Journal* have been given the opportunity of following the work of Dubos, who by a selective method of a tedious and ingenious nature bred out from soil a bacillus producing a substance highly toxic to certain other bacteria, mainly Gram-positive cocci. The crude extract from this bacillus is now known as tyrothricin, and is separable into two components: gramicidin, which acts powerfully but almost exclusively on Gram-positive bacteria, and tyrocidine, which acts similarly but less powerfully on certain both Gram-positive and Gram-negative species. Although known from an early stage to be more toxic than penicillin, these substances have such remarkable properties—and, it may be added, are so much easier to produce—that much more will evidently be heard of them. It is clear from papers now being published in the U.S.A. that the manufacture of gramicidin has been taken up commercially, and quantities are available to a number of workers for various types of study. Toxicity has been investigated further by H. J. Robinson and H. Molitor,[2] who confirm previous observations that, whereas local application and oral administration even in large doses are harmless, the intravenous minimum lethal dose is small. The site of the lethal effect is not clear from their studies, nor do they provide an answer to the question whether the haemolytic activity of gramicidin, recently restudied *in vitro* by D. Heilman and W. E. Herrell,[3] has its counterpart in the living body. This question is perhaps only of academic interest, because all authors seem agreed that local application is the only clinical use for which gramicidin is suited. Heilman and Herrell[4] elsewhere point out an interesting parallel between the action of gramicidin and that of detergents: their selectivity for different bacterial species is similar—even extending to a closer parallel between gramicidin and anionic detergents and tyrocidine and kationic—both are haemolytic, and both are relatively harmless to tissues. These authors have shown this parallel to be even closer by demonstrating that gramicidin and tyrocidine strongly reduce surface tension; this effect, however, persists after heating, whereas bactericidal activity is thus destroyed. In all these studies the very low solubility of gramicidin in water has presented difficulties; an alcoholic solution added to water produces a suspension, and it is in this unsatisfactory form that gramicidin has chiefly been used; how such a suspension will behave in contact with infected tissue is not altogether clear. Herrell and Heilman[5] have prepared a solution for clinical use by introducing glycerin in addition to alcohol as a solvent, and used it in ten miscellaneous cases as a local application. Several lesions due to haemolytic streptococci appear to have cleared up under its influence; staphylococcal infections, on the other hand, are evidently almost wholly resistant. A. E. Francis[6] also records the successful treatment of wound infection in which a sulphonamide-resistant streptococcus was concerned. Whether gramicidin or any other product of microbic origin will eventually be found to fulfil certain purposes better than either sulphonamides or any other class of antiseptic remains to be seen. That several classes of reagent should be competing for supremacy in different aspects of a task which not long ago was considered impossible of any real fulfilment is a truly remarkable position.

AIR DISINFECTION BY LIGHT

Only within the past few years have serious attempts been made to check the aerial spread of infection by disinfecting the air itself. Of the various methods by which this can undoubtedly be done chemical spraying has been most studied in this country, and an adequate basis for a practical campaign is afforded by existing data. In the U.S.A. more use has been made of ultra-violet light, and evidence is accumulating that where this method is employed continuously for long periods the incidence of air-borne infections diminishes. Burners can be installed in such a position as to irradiate only the upper layers of air in a room, and a non-reflecting ceiling ensures that persons in the room shall be unaffected, but convection currents bring the whole of the air within the light field. An exceptionally careful study of the effects of such an installation in a Philadelphia school is described by W. F. Wells, M. W. Wells, and T. S. Wilder.[7] Their observations covered a period of several years, during which irradiation was maintained in some class-rooms and not in others, and careful records were kept of all infectious disease. After detailed analysis the results are expressed as the percentage of susceptible children in each group who developed mumps, chicken-pox, or measles when cases occurred in the same room. The differences in some epidemics were very striking, particularly during an extensive outbreak of measles. In the "unirradiated" classes, consisting of older children, there were 141 (37.2% of the total) with no previous history of measles, among whom 88 cases occurred, an attack rate of 62.4%. Among the irradiated juniors there were 110 susceptible children (75.9% of the total), of whom only 24 developed measles, an attack rate of 21.8%: if home contacts were deducted from these total cases, the attack rates attributable to infection arising in school are 55.3% and 14.5% respectively. Although it has been claimed by others that radiant disinfection of air reduces the frequency of colds, no such reduction was observed in this study, probably because the investigation was made in a day school, and frequent opportunities of infection with the common cold occur at home. It is argued that if the infection were usually acquired in school, and the incubation period is assumed to be two days, the number of colds with onset on Wednesday, Thursday, or Friday would be more than three-sevenths of the total for the week; but records of many hundreds of colds show, on the contrary, that they amounted to slightly less than this fraction. This negative observation is nevertheless disappointing: colds and influenza—which may be expected to behave in the same way—are the chief scourges which air disinfection is designed to minimize. There have been several reports of success in preventing the spread of colds in residential institutions by ultra-violet light. The latest of them is by L. N. Sauer, L. D. Minsk, and J. Rosenstern,[8] who compared the effect of simple air-conditioning, a mechanical barrier, and an ultra-violet-light barrier, in an elaborately equipped hospital for infants. By mechanical barrier is meant that the infant was kept in a cubicle never entered by anyone, and attended to by a nurse through a sliding glass shutter. Either this form of isolation or the use of ultra-violet light clearly prevented cross-infection: the merits of the two systems are discussed. The mechanical barrier is expensive to install, and after a few weeks "a certain lack of stimulation of the infant is occasionally apparent." Ultra-violet light, on the other hand, although less costly to install, is much more so to run.

Direct ultra-violet irradiation of the operation field to ensure surgical asepsis is a proceeding of which much has been heard in the U.S.A., and D. Hart, who has been its chief advocate, has recently with S. E. Upchurch,[9] reported the results of five years' experience with it. His figures, which in sum are very large, give the frequency of infection in clean operation wounds of various types before and after adopting this method, and the improvement is remarkable. Whether it is due, as Hart contends, to the killing of atmospheric bacteria is another matter. In referring on earlier occasions to the work of Hart we have pointed out that his observations on the atmospheric flora of operating theatres are vitiated by failure to apply the coagulase test to staphylococci, and in conflict with those of Devenish and Miles,[10] who found the origin of staphylococcal infection in clean operation wounds to be glove perforations. Hart still makes no reference to these authors' work. So to criticize his argument is not to question his results or the value of his method; it is indeed possible that pyogenic cocci of whatever origin may be destroyed by ultra-violet light in the wound itself. Whether irradiation is capable of this effect is a question which could presumably be decided readily by animal experiment.

THE DRYING OF PLASMA AND SERUM

The Trustees of the late Sir Henry S. Wellcome have placed a sum of up to £20,000 at the disposal of the Medical Research Council for research into methods of drying blood plasma and blood serum to provide stable products for use in the transfusion of patients suffering from haemorrhage, shock, or other conditions calling for such treatment. By agreement between the Trustees and the Council, this gift is to be applied to the purchase, erection, and operation by the Council of a plant which will make it possible to test and develop these methods on a substantial scale. The need for the improvement of such methods is of particular importance at the present time, and the products will be made freely available for the treatment of sick and wounded at home, at sea, and abroad. The Medical Research Council has therefore expressed its appreciation of this timely and public-spirited action on the part of the Wellcome Trustees.

Sir Charles Sherrington, O.M., G.B.E., M.D., F.R.S., has been elected a Trustee of the British Museum.

War Surgery of the Extremities

This is one of a short series of articles based on lectures given at the British Postgraduate Medical School, Hammersmith

BLOOD TRANSFUSION

BY

JANET VAUGHAN, D.M., F.R.C.P.

The problems of transfusion in wartime are inevitably different from those arising in peacetime. In wartime to a large extent we transfuse healthy individuals suffering from sudden severe injury. In peacetime we transfuse sick people. The following discussion applies to wartime transfusions only. It must be remembered, however, that knowledge of the pathology of haemorrhage and shock is extremely limited, and that the teaching of to-day must inevitably be revised as our understanding of the problems involved increases.

Transfusion Fluids

To-day the following fluids are available for transfusion: fresh blood, stored blood, plasma, serum, concentrated red cells.

Fresh Blood.—This has proved impracticable for use under air-raid conditions. In the chaos of modern air raids or warfare it is impossible to call up and bleed donors. Transfusion fluids must be ready in store for immediate use or be brought in from outside the danger area at short notice. Fresh blood is essential for only a small group of chronic cases that do not need immediate treatment.

Stored Blood.—Experience has shown that blood taken into a glucose-citrate mixture will store for fourteen to twenty-one days at low temperature (2° to 4° C.) without undue haemolysis taking place *in vitro*. The survival rate of transfused red cells is not appreciably lower than that of fresh blood. The reaction rate, provided the blood is warmed to 40° C. before use, is no higher than with fresh blood (Brewer, Maizels, Oliver, and Vaughan, 1940). The diluent at present in general use is 100 c.cm. of 3% sodium citrate in distilled water, to which is added 20 c.cm. of 15% glucose in distilled water. The resulting 120 c.cm. is mixed with 420 c.cm. of blood (M.R.C. War Memorandum No. 1).

Plasma.—This may be prepared in three different forms—unfiltered, filtered, and dried. Unfiltered plasma is prepared by siphoning the supernatant fluid off the red cells after sedimentation has occurred by standing or centrifugalization. It is a cloudy fluid which should be kept in the ice-chest. Filtered plasma is passed through a Seitz filter after separation. It is a clear fluid free from cell debris and the fatty content of unfiltered plasma. It must be kept at room temperature, as clotting will inevitably occur in the cold; unless great care is taken in filtration clotting is extremely likely to occur even at optimum temperatures. For the use of the Army, plasma is now being dried by a process similar to that employed for drying serum. The protein content of fluid plasma is only 4 to 5%, owing to the presence of glucose-citrate diluent. The protein content of reconstituted dried plasma depends upon the amount of fluid added.

Serum.—Serum is also available in three forms—filtered, liquid, dry—and as serum citrate prepared from recalcified plasma (Clegg and Dible, 1940). Filtered serum is passed through a Seitz filter after separation of the clots. It is a clear amber fluid with a protein content of approximately 7%. Dried serum is prepared by a modification of the method of Greaves and Adair (1939). It is reconstituted for use by the addition of either distilled water or normal saline, and may therefore be given in varying concentration, depending upon the amount of fluid added. Serum citrate is prepared by the addition of calcium to plasma and filtration of the resulting fluid through a Seitz filter.

Concentrated Red Cells.—This concentrated suspension is prepared by removing the supernatant plasma from the red cells so that double the usual amount of haemoglobin is given in the same volume of fluid. It is no more difficult to administer than whole blood, and is thought to give rise to fewer reactions (MacQuaide and Mollison, 1940).

Before discussing the relative values of blood, serum, and plasma it is necessary to consider the types of case that will need transfusion. They may be divided into acute and chronic conditions.

Transfusion in Acute Cases

The acute group may be roughly divided into three types: (1) patients with haemorrhage so severe as to result in anoxaemia; (2) patients suffering from shock rather than blood loss; and (3) patients with severe multiple injuries and considerable haemorrhage without obvious shock.

1. Severe Haemorrhage

In sudden severe haemorrhage there is a rapid fall in circulating haemoglobin, with resulting anoxaemia. It is then as essential to replace oxygen as it is to restore blood volume, and transfusions of whole blood are required. This type of case has proved rare as a result of air raids.

2. Shock

Shock is a term that includes a variety of conditions which are still poorly differentiated. I use it here to cover those states in which circulatory collapse, lowered body temperature, and pallor occur. It is usually considered to be associated with a fall in blood volume (Whitby, 1941). Treatment must therefore be directed to restoring blood volume. This can only be done by the use of liquids of high protein content. Saline is useless. Gum acacia was employed for this purpose in the last war, but it is difficult to prepare and is apt to cause liver damage. More recently it has been suggested that isinglass (fish gelatin) might be used (Taylor and Waters, 1941). Experimental work on the purification of animal proteins is in progress, but, so far, human plasma and serum have alone proved to be satisfactory for the purpose.

The evidence available suggests that fluid plasma, fluid serum, and dried serum are of equal therapeutic value in the treatment of shock (Vaughan and Brown, 1941). There are as yet few data available as to the effects of dried plasma. In this country no greater reaction rate has been recorded with serum and plasma than with blood. This observation is of some importance, as, with the exception of Levinson, Rubovits, and Necheles (1940), observers in the States regard serum as an almost lethal fluid. In this connexion it should be noted that, while we invariably pass serum through a Seitz filter, this is not done in the States. At the N.W. London Blood Supply Depot there are records of the administration of 147 pints of fluid serum with two mild reactions, and of 367 pints of filtered plasma, also with two mild reactions. Much larger quantities of both have been used in the area, but it is difficult to obtain accurate records under raid conditions. It appears reasonable, however, to conclude that if severe reactions had occurred they would have been reported. In addition to the cases already recorded by Brown and Mollison (1940) we have further details of thirty-four bottles of reconstituted dried serum given without reaction.

Serum would seem to have certain practical advantages over plasma. It is easy to keep sterile, while plasma becomes readily infected. Serum does not clot, but hitherto it has proved extremely difficult to prevent plasma clotting either during or after filtration. The protein content of serum is higher than that of plasma. Further, serum is easy to handle, store, and transport. Plasma has one advantage over serum—namely, that out-of-date blood can be used for its preparation. It therefore seems probable that there is a place for both plasma and serum in any transfusion service.

For the purpose of discussion, cases of "shock" may be divided into three arbitrary groups: shock associated with multiple injuries other than crush injuries; shock associated with crush injuries; and shock associated with burns.

Shock associated with Multiple Injuries other than Crush Injuries.—In this condition there appears invariably to be lowered blood pressure unassociated with haemoconcentration. The pulse may be either rapid or slow. The only reliable guide to the success of any therapeutic measure has proved to be a maintained rise of blood pressure. It is impossible to lay down any hard-and-fast rule as to the dosage required to produce such a rise in pressure. Every case must be treated on its merits. Enough fluid must be given to raise the pressure and to maintain it at a level above 100 mm. Hg. No patient should be allowed to go to the operating theatre with a pressure that is much below 100 mg. It should be remembered that three or four pints of fluid, or more, may raise the pressure when one or two have failed. It would seem from our own published figures that many cases of circulatory collapse may be satisfactorily treated by blood derivatives, but whether, alone, they are preferable to whole blood remains to be seen. We have been struck by the occurrence of relatively low haemoglobin readings in patients with traumatic shock resulting from enemy action who have had no gross and obvious source of haemorrhage. Also, patients who have been successfully treated with plasma or serum have on subsequent examination shown haemoglobin readings in the neighbourhood of 60%. Such preliminary observations suggest that the ideal treatment for a patient suffering from air-raid shock may be one or two bottles of plasma or serum followed by one or more bottles of blood, the treatment being controlled by repeated haemoglobin and blood-pressure readings. This procedure has been carried out successfully in a large number of recorded cases.

Shock associated with Crush Injury.—A series of cases of crush injuries associated with renal failure have recently been described (Bywaters and Beall, 1941; Beall, Bywaters, Belsey, and Miles, 1941; Mayon-White and Solandt, 1941) The pathology of this condition is not for discussion here The treatment still remains uncertain and, with few exceptions, unsatisfactory (Longland and Murray, 1941; Henderson, 1941). It is important to remember that haemoconcentration in this condition may be pronounced. Figures as high as 160% have been recorded (Bywaters and Beall, 1941). It is obvious that in such a case serum or plasma should be used instead of whole blood. The amount to be given must be decided afresh for each case, the blood pressure and haemoglobin being used as the guide to dosage. The gross waterlogging of the tissues found at necropsy in some of these cases after massive saline transfusions suggests that saline is to be avoided.

Shock associated with Burns.—Shock associated with severe burns is characterized by haemoconcentration, which may be severe. In a series of 13 cases of burns seen by Dr. Brown haemoconcentration was present in all those in which observations were possible, with one exception. In that case the patient was seen within twenty minutes of the injury. At this time both blood pressure and haemoglobin were within normal limits. Two pints of serum were given, and neither haemoconcentration nor fall of blood pressure occurred. It is, however, exceptional to see a patient so soon after injury. In burn shock, *par excellence,* there would seem to be a special call for the use of either plasma or serum, as fluid of a high protein content must be given to restore and maintain the blood pressure at a normal level. Repeated haemoglobin estimations may be impossible owing to the extent of the burnt area. If they can be done, however, they offer a valuable additional guide to dosage. Cases of burn, even if they have a normal pressure when first seen, should be immediately transfused; prevention is better than cure. Transfusions should begin before the patient is taken to the operating theatre to be cleaned up, and if the burnt area is extensive should be continued throughout this process and, if necessary, when he has returned to the ward. Subsequently intravenous therapy must be determined by the patient's condition.

3. Severe Multiple Injuries and Haemorrhage

Grant and Reeve (1941) described a group of cases in which there was normal blood pressure in spite of severe multiple injuries and haemorrhage. Out of a group of 100 cases 28 presented this picture, and of these only 6 did not finally receive transfusion. In 13 cases the blood pressure fell considerably and the pulse rose within four hours of admission. In most the collapse occurred before operation, in a few it was delayed until during or after it. Transfusion was followed by rapid improvement. In 9 of the patients transfusion was started soon after admission, though the blood pressure was not low, and the condition remained satisfactory except when further bleeding occurred. As with burns, early transfusion prevents later collapse in severely injured cases. In other words, our guide in resuscitation work should be in the severity of the injury sustained and not the blood pressure or pulse level. Patients with multiple injuries and severe burns must be transfused as an urgent method of resuscitation. It is wiser to prevent circulatory collapse than to treat it. Patients in this group respond well to serum or plasma as an initial dose, but probably should receive blood in addition when it is available.

Transfusion in Chronic Conditions

The following two groups of patients require transfusions in the later stages of treatment: (1) those with burns, and (2) those with septic wounds.

Burns.—Localized oedema often occurs in the neighbourhood of a burnt area twenty-four hours after injury. There is some evidence that this may be reduced by the administration of twice-concentrated or four-times-concentrated serum. It would appear wise to continue to give concentrated serum so long as oedema persists, unless the patient becomes intolerant of fluid by mouth; in such cases normal serum is preferable. In the late toxic stages, when sepsis has become an important factor, whole fresh blood should be given, if necessary, in large repeated doses by a drip technique. Satisfactory healing is dependent to a large extent upon maintaining an adequate haemoglobin level.

Septic Wounds.—Patients with infected wounds often show considerable anaemia. This is unaffected by the usual haemopoietic remedies (Vaughan and Saifi, 1939). Plasma proteins are also usually low. It is essential to raise both the haemoglobin and the plasma protein level in such patients if satisfactory wound-healing is to take place. This is done by repeated large transfusions of fresh whole blood. These transfusions should aim at raising the haemoglobin level to 100%. Several pints may be given by drip technique during twenty-four to forty-eight hours Having raised the haemoglobin it must be maintained at an optimum level. Concentrated suspensions of red cells are useful for this purpose, especially in elderly subjects in whom it is important not to increase the blood volume.

Some Technical Points in Transfusion

Temperature of Administration.—If circumstances permit it is wiser to warm blood, plasma, or serum to body temperature before administration. This can be done by standing the blood-bottle in water at 40° C. for twenty minutes and mixing it gently at intervals. Under air-raid conditions it is often necessary to give the first bottle cold, but while this is being done the second can be warmed.

Rate of Administration.—With a young patient it is probably safer to give large quantities of fluid rapidly than it is with an older patient, but again it is difficult in our present state of knowledge to lay down any hard-and-fast rules for guidance. When the patient fails to respond to two pints of fluid administered rapidly, a careful watch should be kept on the base of the lungs if further rapid transfusion is considered. In practice we give the first two pints rapidly, using a reversed Higginson syringe to apply pressure if necessary, and subsequent fluid more slowly by drip technique. It should be remembered, when it is necessary to use the veins in the leg, that these are likely to be extremely collapsed, especially in the badly shocked patient, and that pressure is essential to start a flow of fluid. After the first pint the flow can usually be maintained by simple gravity.

Filtration.—Stored blood and derivatives should always be passed through a filter before administration. The routine administering unit in this country is fitted with such a filter. A fatality has recently been recorded in the States from giving unfiltered plasma (Mayner, 1941). At necropsy fibrin plugs were found in the lung capillaries.

Cross-matching.—It is the usual practice in this country at present to issue universal donor blood only. Theoretically, therefore, it should not be necessary to cross-match the cells of the donor with the serum of the recipient. When possible, however, it is wise to do this, as errors in grouping cannot always be avoided and such a cross-match serves as a double check. In the case of serum and plasma no cross-matching is necessary. Both serum and plasma are prepared from pooled supplies, and it is found that as a result the agglutinin titre becomes either negative or so low as to be insignificant. Even in the early days of plasma transfusion in this country, before pooling was carried out, it was found that no ill effects followed the transfusion of a Group B donor, for instance, with large quantities of Group A plasma, and vice versa.

Transfusion Reactions

The ideal transfusion should have no effect on the patient beyond improvement; reactions may, however, occur. They take various forms, varying considerably in severity. The mildest type shows a slight rise in temperature; in others there is a severe rigor, often associated with a pain in the back, vomiting, and headache or generalized urticaria. In some instances in which incompatible or grossly haemolysed blood has been given there is a haemolytic crisis, resulting, unless promptly treated, in death. When a severe rigor occurs, the question at once arises whether the transfusion should be stopped. Every case must be decided on its merits; in a severely anaemic patient, or a shocked air-raid casualty it is wiser to continue the transfusion in spite of the rigor. In the less acute case the transfusion may be stopped

In the case of an incompatible transfusion, prompt measures must be taken if the patient's life is to be saved. It is essential to maintain an alkaline urine. Alkali should be given by mouth and, if necessary, by intravenous injection. The patient should be catheterized twice a day if there is retention. It should not be assumed that failure to pass urine means complete anuria. Fluids, especially glucose solution, should be given in large quantities, if necessary per rectum or intravenously.

Summary

The use and relative value of whole blood, serum, and plasma for transfusion purposes are discussed.

Whole blood is preferred in acute severe haemorrhage; plasma and serum in conditions associated with haemo-concentration—i.e., burns and certain cases of crush injury; and a combination of plasma and serum, with whole blood, in patients with severe multiple injuries.

In the case both of burns and of injuries the severity of the injury and the degree of blood loss rather than the blood pressure and pulse should indicate the necessity for transfusion.

No rules for the precise dosage of any transfusion fluid can be laid down. It is essential to raise and maintain the blood pressure over 100 mm. Hg. The dose required to do this is extremely variable.

Serum and plasma appear of equal clinical value, and both are non-toxic. Serum has certain practical advantages over plasma.

ACCELERATED MEDICAL COURSE AT TORONTO

The acceleration of the medical course at the University of Toronto to meet the shortage of doctors for the armed Forces and for civilian needs was decided upon in the spring of 1941. The proposed curriculum consisted in lengthening the academic session from 7½ to 10 months in all years of the course but the first, which is made up of pre-medical subjects. This procedure will ensure that a class of students graduates every eight months instead of every twelve as at present. As it has been thought essential that each graduate should have a period of interneship in a hospital in order to round off his education, either to begin private practice or to become a medical officer in the Forces, the hospitals were asked if they would shorten the interneship period from 12 months to 8 months so that medical officers might be made available for military service as quickly as possible and at the same time provide for the co-ordination of the interneship period with the graduation of students every 8 months. Provincial licensing bodies were requested to permit the medical curriculum to be completed in a shorter time than their regulations required. Both the hospitals and the licensing bodies agreed to the proposed changes as a war measure.

University of Toronto Course: Graduation, Interneship, Military Service

1941–2	Graduation	Interneship	Available for Military Service	
			Speeded-up Course	Regular Course
6th Year ..	Apr. 30, 1942	May 1, 1942 to Dec. 31, 1942	Jan. 1, 1943	July 1, 1943
5th Year ..	Dec. 31, 1942	Jan. 1 to Aug. 31, 1943	Sept. 1, 1943	July 1, 1944
4th Year ..	July 30, 1943	Sept. 1, 1943, to Apr. 30, 1944	May 1, 1944	July 1, 1945
3rd Year .	Apr. 28, 1944	May 1 to Dec. 31, 1944	Jan. 1, 1945	July 1, 1946
2nd Year ..	Dec. 31, 1944	Jan. 1 to Aug. 31, 1945	Sept. 1, 1945	July 1, 1947

The accelerated curriculum at Toronto came into operation when the second- to sixth-year classes registered on Aug. 25, 1941, the effects of which are shown in the accompanying table. As the result of this speeded-up curriculum, the sixth-year class will take the place of the present class of internes in hospitals on May 1 instead of July 1, making them available for military service 2 months earlier than would ordinarily be the case. This present sixth-year class will be available for the Forces on Jan. 1, 1943, instead of July 1, or 6 months sooner; the fifth-year class will be available 10 months, the fourth-year 14 months, the third-year 18 months, and the second-year 22 months earlier. The curricular changes in the courses of each of the years have been only of a minor character, the time-tables in each year consisting of the three terms of the present course, to which has been added the first term of the next succeeding year, in the fourth term from April to June. The total length of the actual instruction is such that each student receives practically the same sound medical training as in the regular course, but in a shorter period.

Correspondence

Post-war Medical Reorganization

SIR,—There are few members of the medical profession who will not have read, with interest and profit, the Interim Report of the Medical Planning Commission, to which document you have so rightly given first place in your issue of June 20. Being an interim report, published for the purpose of stimulating discussion within the profession, it is not comprehensive, and, for the same reason, the proposals contained in it are capable of amendment.

Writing as a member of the public health service I should like to express the view that the fundamental principles underlying the report, such as central control by the Ministry of Health or a similar body, and administration by enlarged local authorities or *ad hoc* regional bodies, are sound and worthy of support by the profession as a whole, including those engaged in the public services. It is, however, important, when the scheme has been fully discussed by the profession and is presented in its final form, that we should make up our minds which of the various alternatives we wish to support. Should the scheme be administered centrally by the Ministry of Health or by a specially appointed body, and at the periphery by local authorities or by newly formed authorities created for this purpose only? These points are not matters of detail, as the success of any scheme involving such a complicated issue as the integration of all the present medical services into one complete system depends largely upon the suitability and competence of the bodies chosen to supervise and administer it.

The report itself suggests the answer to one of these questions when it emphasizes that "the system under which local authorities administer in detail a broad national policy decided by the central Government is deeply embedded in the social fabric of this country." This would seem to be a conclusive argument in favour of peripheral administration by enlarged local authorities appointed for all purposes, and there is the further reason that the present major authorities have already co-ordinated some of the medical services which are referred to in the report, including their hospitals, many of the personal health services, and the services concerned with environmental hygiene. Moreover, the influences favouring a satisfactory condition of health within the community are by no means wholly medical. Apart from questions of nutrition and standards of living, which are only slightly influenced by the action of local authorities, there are such matters as housing, education, the provision of baths and wash-houses, abattoirs, parks and recreation grounds, crematoria, etc., all of which in the hands of local authorities play a part in affecting favourably the health of individuals living in urban communities. On its merits the argument for allowing local authorities to take a share in the administration of the new medical service seems a sufficiently strong one; but, apart from this, it would seem to be politically wise to enlist the support of the powerful influence of the local authorities in favour of the profession's agreed scheme rather than to risk disaster by provoking their equally powerful opposition. On the whole the major local authorities, if of sufficient size and possessing adequate rateable value,

P 25508.

are efficient administrative bodies within the limits of their legal powers; they possess other services, apart from those dealing with public health and hospitals, which are of great assistance to a medical department; and their members, becoming keenly interested in health problems, form committees which, as a rule, are just as efficient in discharging their duties as would be the theoretically more perfect regional councils suggested in the interim report as an alternative.

I would emphasize that the essential things are size and rateable value. A drastic reorganization of local government areas is long overdue, but if the Government after the war performs this essential task adequately the units thus formed should be perfectly capable of playing their part in the new medical organization. The medical services in each area would then, in some respects, be analogous to the education service of the present day. The local authority would provide, equip, and maintain health centres on the basis of a grant from the Exchequer just as it now provides schools on the same basis. It would possess a statutory committee, similar to the education committee or the public assistance committee, to which all questions relating to the public medical service would be referred. In the interests of the medical profession, arising out of the more important interests of the patient, the local authority would be strictly controlled by regulations made by the appropriate Government Department in regard to its relations with the medical personnel in its area. Under any scheme for improving the manifest inefficiencies of the present system some increased measure of State control is essential. If that control is directly exercised from Whitehall or indirectly maintained by regional offices under the Ministry there will ensue a full State Medical Service with all the manifold disadvantages in loss of freedom to the profession which such a system entails. If, on the other hand, a less rigid system of control, designed to make the system work but not to cramp initiative, were entrusted to enlarged local authorities under regulations framed to provide as large a measure of freedom as possible to the profession, the objective which the Medical Planning Commission has before it might be attained. Much would still have to be done by the central authority, and the interim report is by no means clear as to the machinery to be used by that body for the transfer of practitioners, including consultants, from one area to another, to ensure the provision of satisfactory hospitals in all parts of the country, to coerce backward or unsatisfactory local authorities, and to obtain consultation between neighbouring local authorities in regard to matters of common interest. It is certain, however, that the performance of functions of this kind, together with the control of the financial aspects of the new service, the issue of regulations, and the supervision of the activities of the major local authorities, would necessitate the formation of a strong division at the Ministry of Health administered by a principal assistant secretary and a chief medical officer.

In discussing or considering post-war medical reorganization one is always confronted by the problem of reconciling the increased measure of State control, which is essential if any comprehensive public medical service is introduced, with the freedom of the medical profession. Ordinary safeguards incorporated into a Medical Services Act might be gradually relaxed in amending Acts as time went on. A safeguard of a permanent character, unlikely to be weakened so long as our political system remains similar to what it is now, would be the placing of responsibility for the detailed administration of the co-ordinated medical services in the hands of enlarged major local authorities. Other but less effective safeguards would be the continuance of some voluntary hospitals and of a limited amount of private practice and the survival of the General Medical Council in something like its present form.—I am, etc.,

Liverpool W. M. FRAZER.

"Positive Health"

SIR,—In the Medical Planning Commission's Interim Report they put as a first aim of a medical service the "achievement of positive health." The phrase is a little unusual and it is essential to be perfectly clear what it means. I take it to mean a degree of health at or above the average, so that, for example, I may be said to be in a condition of "negative health" during the day following a night of hard work. If I am right in this surmise—and if I am not I hope some member of the Commission will correct me—the phrase amounts to the promotion of personal hygiene. If this be so I am sure everyone will support the aim, provided the idea is never carried to the length of any suggestion of Government interference with personal liberty as, for example, in the prohibition experiment in America.

But I would submit that the subject of personal hygiene is still in the pre-scientific stage. We all try to inculcate it on our patients, incidentally often on the lines of "Do as I say and not as I do," and it remains too true that in this respect "a man of 40 is either a fool or his own physician." Personal hygiene is the happy hunting-ground of faddists and fashions. It seems to me that before the aim becomes an achievement personal hygiene will have to be erected into something of a science by the old methods of long, laborious, and completely unprejudiced research.

Let us not lead the public to suppose that we can confer the great gift of exuberant health.—I am, etc.,

Dover. A. R. JORDAN.

The Pre-natal Clinic

SIR,—The war is sometimes blamed for conditions which might be more correctly ascribed, at any rate in part, to our lack of enterprise. Perhaps it was inevitable in 1939 that the educational side of our health services should largely go to the wall, but the time has come when it is more than ever necessary to resume our health teaching. Pending the introduction of mothercraft classes in schools, it is important to concentrate upon the teaching of mothercraft in our pre-natal clinics. The young expectant mother is an exceptionally receptive subject for this teaching and welcomes it when it is provided.

What is to be avoided is the "hospital atmosphere" still too often associated with the pre-natal clinic, and the handling of expectant mothers as though they were a pack of cards. What do we find but a long row of women waiting on benches "to see the doctor," whispering tales of complicated confinements to each other, and exchanging accounts of their own symptoms which each tries to make more sensational than the last. The influence of suggestion is marked; on some days there is an epidemic of pain in the legs, on another frequency of micturition, and on a third abdominal cramp. Nearly always the attention of the woman is focused on a physical symptom rather than on the proud expectancy of childbirth. And the visit to the clinic is synonymous to her with getting on a couch to have her abdomen palpated "in case anything is wrong."

Surely the psychological effect of a clinic run on the above lines cannot be right. Pregnancy is not a disease of nine months' standing. It is a physiological condition and should not be associated with the idea of illness. The expectant mother is not a case or a patient. From the moment the mother enters the clinic she should receive instruction combined with entertainment, the programme of training for her new role of motherhood being made as interesting as possible. Medical supervision is necessary and desirable, but should be carried out without ostentation and with a cheerfulness as far removed as possible from the "bottle of medicine" line of approach. The doctor must certainly examine to ensure that the mother is obstetrically fit; although, once the pregnancy is found to be normal and the date of confinement confirmed, the frequency of abdominal palpation, so often purposeless, now in vogue is unnecessary. The health visitor will help her to make arrangements for the confinement and the hospital sister will give the requisite instructions; but these will be sandwiched in with the dressmaking stall, the cookery demonstration, and the class for physical exercises, the rhythmical dance music from the latter pervading the clinic and proving an excellent antidote to any thoughts of backache.

Reformers are seldom appreciated in their lifetime, but we hope that an exception may be made, in the case of Dr. Kathleen Vaughan, whose book *Safe Childbirth* is such a valuable contribution. It is under Dr. Vaughan's personal supervision that physical exercises to train expectant mothers for childbirth have been conducted at Paddington (L.C.C.) Hospital since last September, and are proving very popular. The prospect of "radiant motherhood" shown by these girls, laughing together as they swing their limbs in unison to the gramophone, is one of the happiest sights imaginable. Further classes are now being established as ancillaries to the clinics of St. Mary Abbots (L.C.C.) Hospital and to those of the Kensington Borough Council.

It is submitted that these classes in physical exercises, including relaxation, mark a considerable forward advance in obstetrics. Hitherto there has been too much acquiescence in the increasing difficulty of labour. If our nation is to play a leading part in the world of the future, it is necessary to produce a healthy and prolific post-war generation. This is not likely to come about if childbirth is regarded in the same light as a surgical operation. Why not determine to bring it back to the normal event which it still is in races whose women lead less sedentary lives?

Physical exercises must, of course, be combined with proper feeding, and few would question the desirability of food advice bureaux at the pre-natal clinics. Here the expectant mother obtains advice on dietetics together with practical and topical hints on cookery. The pioneer of these bureaux was established at the Soho Hospital for Women in October last, where a cooking demonstration is held for the waiting out-patients. In the clinics of the Kensington Borough Council a trained dietitian of the London County Council working in co-operation with the Ministry of Food has kindly lent her services for this purpose and gives short demonstrations to the mothers, followed by an informal discussion. At Paddington and St. Mary Abbots (L.C.C.) Hospitals such bureaux have been started in the ante-natal departments and the mothers are very appreciative of this service. A third point on which useful advice can be given to the expectant mother is in the matter of baby clothes. Wool, bought at a reduced price and sold in the Kensington Welfare Centres, makes a useful opening for demonstration of the best types of infants' garments and often develops into a knitting or sewing class.

Clinics on such lines fill a definite need of the pregnant woman and afford the means of keeping her under unobtrusive medical supervision and guiding her into healthy ways of living. The health visitor and hospital almoner can help her in her troubles and get her into touch with any organization whose assistance she may need. And the society of other young mothers affords the opportunity of lasting friendships. It is undoubtedly more trouble to organize a clinic on such lines in wartime, but the wives of our men in the Services deserve the best we can give them. Those of us who perforce have to remain at home have a duty in this respect. And is it not the best way to keep up morale of those at the front to give their wives a fair deal? It is to be hoped that all clinics for the expectant mother of the future, whether at hospital or health centre, will be run in a way which emphasizes the ideal of health and not the idea of disease and in which constructive hygiene as preached and practised by Dr. J. S. Fairbairn is given foremost place. In this atmosphere the doctor escapes from what Prof. Charles McNeil (April 4, p. 479) has so aptly described as "the deadening effect of the treadmill of clinics."

The writers of this letter must add the usual disclaimer on behalf of their respective councils of any responsibility for their personal views. They would like to express their gratitude to Dr. W. Allen Daley, Medical Officer of Health of the L.C.C., for his interest and granting facilities, and to Dr. James Fenton, Medical Officer of Health of Kensington, for his help and encouragement.—We are, etc.,

WILLIAM C. W. NIXON.
London. VIOLET RUSSELL.

Medical Women in the Forces

SIR,—Referring to my previous letter (April 18, p. 505) regarding the status of women doctors serving with H.M. Forces, I stated that medical women volunteering for service under the Army Council were offered two alternatives: (*a*) relative rank with the R.A.M.C. without commission, or (*b*) a commission in the Women's Forces to serve with the R.A.M.C., and that in the circumstances the Medical Women's Federation considered that "relative rank" only was preferable.

The Federation has since been informed that medical women will not in future be permitted to choose relative rank without a commission, but must be given a commission in the Women's Forces—i.e., they receive a commission in the Women's Forces to serve *with* the R.A.M.C. (a medical man receives a commission in the Land Forces to serve *in* the R.A.M.C.). We shall be glad if publicity can be given to this decision in order to avoid further misunderstandings.

The position as regards medical women serving with the R.A.F. Medical Branch has also now been clearly defined. The women are obliged to accept commissions in the Women's Forces to serve with the R.A.F.M.B. The appointments are gazetted as "To be Medical Officers with the relative rank of Flying Officer for employment with the R.A.F.," and they are shown in the Air Force List as "Women Medical Officers commissioned for employment with the R.A.F."—I am, etc.,

CLARA STEWART,
President, Medical Women's Federation

Inhibition of Lactation

SIR,—Drs. Macpherson and Haultain have done right to draw attention to their previous reports, which I gladly acknowledge, on the use of triphenylchloroethylene and other oestrogenic substances for inhibiting lactation. In her paper on this subject (*Journal*, May 16, p. 601) Miss Barnes mentioned the first investigation by Macpherson and Robertson, and at the time of preparation the most recent work by Haultain and Macpherson had not been published. My letter was intended as an addendum to Miss Barnes's paper, and I therefore did not introduce new references, although I now regret the omission.

Although in my experience the drug, when injected in a single dose of 250 mg. in 5 c.cm. of sesame oil (first tried in a few cases two years ago and repeated again recently), has not given such good results as those reported by the Edinburgh workers, we all agree that oral administration in suitable dosage has an excellent effect. There is no doubt that the use of synthetic oestrogens for the inhibition of lactation has supplanted the older uncertain and painful methods of treatment.—I am, etc.,

Oxford CHASSAR MOIR.

Complacency in Anaesthetics?

SIR,—Dr. E. C. Atkinson (June 20, p. 774) has asked whether any large-scale statistics are available of immediate mortality under anaesthesia apart from any added factor such as the magnitude of the operation or the poor condition of the patient. In other words, he asks for the incidence of primary cardiac failure due to anaesthesia.

It is now recognized that with a competent anaesthetist using modern techniques this event is so rare that an immense number of cases must be handled to obtain any reliable figures. Anaesthesia for dental extractions has been studied from this angle, and at large children's hospitals many thousands of cases are dealt with yearly without accident.[1] The usual techniques are open ethyl chloride or divinyl ether. One series of 123,000 consecutive cases with the former drug has been reported without incident,[2] as has another of 125,000.[3]

The mortality rate of expertly given nitrous oxide and oxygen for dental extractions is also infinitesimal. For example, 1,161,820 dental cases were anaesthetized with this method with 2 fatalities, a mortality rate of 0.00017%. Another series of 300,000 has been reported with no deaths.[4]

I believe that the vast majority of primary cardiac failure cases are due to gross errors in technique or to the employment of chloroform or a mixture containing it. With the advent of trichlorethylene the number of occasions when chloroform is justifiable is almost zero.—I am, etc.,

St. Albans, Herts C. LANGTON HEWER.

SIR,—Dr. E. C. Atkinson (May 9, p. 595, and June 20, p. 774) appears to have laid himself out to criticize the McKesson machine. Why the machine? Surely he cannot blame a machine for any death. The machine is worked by someone, however incompetent, and the administrator is the one to blame, if there is any blame. I am afraid that, when this machine came out a very large proportion of men considered it to be quite foolproof, and with a certain number to-day that opinion is prevalent. It is far from being foolproof; I cannot conceive of any mechanical device being foolproof. I have seen a McKesson worked many times by men who were grossly incompetent and who got into trouble. Recently I met a man who had been using a McKesson for several months and asked me where the bags were. During that period he had not even learned the mechanism. I should think he was about due for a death or two and then would promptly blame the machine.

I have heard criticisms like Dr. Atkinson's many times, but usually from men who either have never owned a machine or only use one occasionally: never from men who use it constantly and are in a position to criticize it. May I draw Dr. Atkinson's attention to the very convincing letter by Dr. Freda Bannister (March 14, p. 367) and also the one by Dr. Massey Dawkins (May 23, p. 653)? I have used McKesson machines since 1926 and my results are far better than they were under the "rag-and-bottle" regime. The "rag-and-bottle" method may be fairly safe on the table, but what about the after-effects? The opponents of the machines are usually silent on these matters. The McKesson is, to my mind, the Rolls Royce of machines, as stated by Surg. Cmdr. H. Parry-Price (June 13, p. 738), but it is certainly not foolproof and cannot be blamed if it is used by incompetent people.—I am, etc.,

J. B. H. HOLROYD, D.A.,
Anaesthetist, Sheffield Royal Infirmary.

Vitamin B and Toxaemia of Pregnancy

SIR,—The article by Prof. W. C. W. Nixon, Dr. Margaret Wright, and Mr. E. C. Fieller (May 16, p. 605) was of great interest to us in view of the following case.

A primigravida aged 19, attending the ante-natal clinic of this hospital, was apparently normal until 33 weeks, when her blood pressure was 130/86, previous readings having been about 120/70. She did not attend when requested, and her B.P. was found to be 190/120 at 37 weeks, and she had albumin + + in the urine. She felt fit and well, but came into hospital on being pressed, afterwards admitting that her face, body, and legs had swollen noticeably. Conservative treatment as follows was started immediately: (1) Complete rest in bed, with a radiant heat bath for 20 minutes twice daily. (2) Nothing by the mouth beyond barley-water or marmite prepared as a beverage, pot. cit. gr. lx four-hourly, and mag. sulph. ʒij twice daily. (3) Enemata as required to maintain frequent stools.

After two days as above she was allowed sandwiches of marmite or grated raw carrot, first one of each per meal and later almost *ad lib.* A small amount of fish and chicken was then allowed to relieve the monotony. The main part of the food taken was marmite—i.e., vitamin B_1—in one or other form. The result was surprising. The blood pressure fell from 192/120 to 186/96 over-night, then to 166/110, 130/90, 130/86, 130/90, 130/86, 130/84 on successive days, and the albuminuria and oedema disappeared completely. At her own request she was allowed home under medical supervision. When readmitted in labour her blood pressure was 144/90 and there was albumin + in the urine. Labour and puerperium were normal and she was albumin-free on discharge, with blood-pressure 112/76. The placenta incidentally had four white infarcts, two of which were over 2 inches in diameter, and the whole maternal surface was studded with pin-head size calcified punctations.

The paper referred to above suggests that vitamin B_1 might be beneficial in pre-eclampsia. This case would appear to indicate that some part of the B complex is in fact strikingly beneficial. I have to thank Mr. R. Everett, F.R.C.S., M.R.C.O.G., for permission to publish this case.—I am, etc.,

WALTER CALVERT,
Resident Obstetrical Officer, Victoria Hospital, Blackpool.

The Mesentery in Regional Enteritis

SIR,—While the role of the mesentery in the development and dissemination of this lesion remains obscure, speculation is rife. Mr. Norman Tanner (June 13, p. 739) ranges himself beside those who regard the changes in the intestinal wall—ulcerative and hyperplastic—as secondary to lymphatic obstruction with mesenteric lymphadenitis; and he cites the oft-quoted experimental evidence of Reichert and Mathes in support of this theory of causation. These workers, it is well known, produced lymphoedema (hardly described correctly as "elephantiasis") in the bowel wall of dogs by the injection of sclerosing solutions into the mesenteric lymphatics. When the animals were killed some months later neither the characteristic ulceration nor fibrosis of regional enteritis was found, and apparently they were driven to the assumption of a "chronic low-grade bacterial infection" to explain these features of the human lesion. All of which seems rather like begging the question of aetiology, inasmuch as not a tittle of evidence has been produced about the nature of the hypothetical infection, bacterial, protozoal, fungal, or viral. Each species in turn has been incriminated as the causal agent—viruses seem to hold the field at the moment—but no proof of any has been forthcoming.

Mr. Tanner also emphasizes the obvious importance of removing the thickened mesentery and its glands along with the diseased gut. "The highest visibly affected segment" is an uncertain guide to this, for we have no knowledge whatever of the earliest stages of the process such as are incapable of detection by the naked eye. In practice we have found great difficulty in determining the true extent of the affected bowel, and believe that this failure to appraise accurately the limits of the disease at the first intervention is responsible for some of the recurrences after a "radical" operation. Even the so-called skip areas may be a snare, masking wide submucous extension of the condition beyond visible changes in the bowel wall.

En passant, has not the time arrived for the adoption of a uniform nomenclature descriptive of this clinical entity? Of the two titles used for it by Mr. Tanner, that which I have employed above seems preferable, though this is only a personal view. Eponyms abound in medicine, and it is unfortunate that they do, for they are often inaccurately assigned and as often invidious in choice. One pertinent example of this may suffice. The fact that Crohn and his associates rediscovered in 1932 a lesion which Dalziel (*Journal,* 1913, **3,** 1068) fully described with a wealth of pathological detail in 1913—incidentally in a paper read at the Annual Meeting of the British Medical Association—is surely not evidence of the existence of "Crohn's disease." In the interests of accuracy I think this term should be abandoned.—I am, etc.,

Ashton-under-Lyne F. G. RALPHS.

Tetanus after Sulphonamide Treatment of Cavities

SIR,—In view of the increasing application of sulphapyridine and sulphanilamide powder to septic and potentially septic cavities, and particularly to the peritoneum in peritonitis, I think I am justified in drawing attention to an inquest reported recently in the *Pharmaceutical Journal* (May 30), which I have not noticed published in the medical journals.

Briefly, a married woman of 34 was operated on for an unspecified pelvic inflammation on April 13. Free pus was found in the pelvic peritoneal cavity and sulphapyridine powder sprinkled therein. There are no details of what drainage was employed. On April 20 the patient developed tetanus and died the next day. The pathologist confirmed the presence of tetanus in the tissues. He examined the catgut, with negative results. In the cardboard of both containers of the sulphapyridine he found tetanus and in the actual powder from one of them.

Further evidence called disclosed that the powder had not been sterilized, but handed to the surgeon in a sterile swab. The medical consultant to the firm supplying the drug drew attention to the fact that printed on the label of the container was the advice: "The contents of this package have not been sterilized." He recommended sterilizing at 160° C. for 20 minutes. I believe, from the fact that in case reports of the use of this drug in operative surgery its sterilization is not stressed, that it is generally held that it is not necessary to sterilize it. I have seen it used straight from the packet in two or three hospitals and have used it so myself, believing that being a mild antiseptic it would not contain viable germs. For its application in surface work—skin grafting and extensive surface lacerations, for instance—sterilization is probably unnecessary, as tetanus rarely develops in such sites. But in view of the above case its use unsterilized in deep cavities, the peritoneum, and the wound resulting from a perineal excision of the rectum would appear to be very dangerous, as these sites favour growth of anaerobes.

Apart from the possibility of tetanus, the other question that the report raises is the use of the powder in the presence of free pus. Apparently it is contraindicated in these circumstances, because the chemical is inactivated by the pus. But is its use definitely harmful? One hears from time to time of its successful use in apparently hopeless cases of fulminating peritonitis with much free pus present. Is it justifiable in these desperate cases to calculate a maximum dose, based on the patient's weight and supposed tolerance under the circumstances, and put it in the peritoneum, assuming that half or more will be neutralized by the free pus and the remainder be available for action in the blood stream? If such a procedure is considered justifiable a routine full course of intramuscular pentnucleotide (Smith, Kilne, and French) might be started immediately.

It would be interesting to know whether any of the newer sulphonamides—succinyl-sulphathiazole and sulphaguanidine—now recommended for intestinal conditions and considered very little toxic would be better received by the peritoneum and more effective, owing to their selective action on the harmful bacteria of the intestinal tract.

At all events, it is obvious that in future sulphonamide powders must be sterilized carefully, and the statement in *The Surgery of Modern Warfare*[1] attributed to J. H. Key and T. H. Burford that "sterilization of the crystals does no harm but is unnecessary" must now be considered obsolete.—I am, etc.,

St Ives, Cornwall E. C. ATKINSON.

Urethral Instrumentation

SIR,—I wish to support Mr. Clifford Morson's plea for more efficient instruction in the use of urethral instruments (June 20, p. 771). There is, however, one statement in his letter which cannot be allowed to pass unchallenged. Surely it is not true to say that "a general practitioner will *benefit* his patient . . . by passing a catheter" in a case of acute retention. There are many dangers associated with this apparently simple procedure, not all of which will be obviated by efficient training.

Let us assume that the practitioner is able to avoid making a false passage and that his aseptic technique is above reproach, there are still the dangers of complete anuria and of haemorrhage, either from the kidneys or from the bladder, as the result of a too sudden decompression. It would probably be of more value to teach senior students when *not* to pass a catheter; acute retention due to an enlarged prostate would come at the head of the list. In my opinion such a case should be treated as an acute emergency and admitted immediately to hospital or nursing home before the retention is relieved.

I can recall many cases, as no doubt can Mr. Morson, where catheterization has added very considerably to the difficulties of the surgeon. This is particularly true of cases that are suitable for the perurethral operation by the Thompson punch or McCarthy's electrotome. In my experience this operation is not infrequently contraindicated as a result of interference by the practitioner.—I am, etc.,

Reading GORDON L. BOHN.

Bacteriophage for Bacillary Dysentery

SIR,—I am very glad to observe the satisfactory report by Dr. Arthur Compton (June 13, p. 719) of the bacteriophage treatment of bacillary dysentery in Alexandria. It is, however, perhaps unfortunate that his paper had to be abridged as a war economy, since it is evident both from the paper and from results achieved in this country that despite earlier forebodings there is a future for this form of therapy. One would have liked more details of the actual form of administration and the source and potency of the bacteriophage used to compare with those adopted here in Britain. A considerable number of cases for which I have prepared and used both autogenous and stock bacteriophages in this country have obviously not allowed any number of dysenteries to be included; in fact the work has been largely carried out on staphylococcal cases and some various toxaemias associated with intestinal bacilli. Suffice it to say for the moment that the results are as satisfactorily significant and interesting as to be compared with advantage with those of modern chemotherapy with sulphonamides.

Results such as are reported by Dr. Compton must be of the greatest importance, and should be emphasized as an effective and rational form of treatment, especially in view of the very large concentrations of men in the Forces now in that country and among whom such epidemics must be rapidly controlled and effectively treated. To this end Morison even reports the prophylactic use of bacteriophage in well-water in Assam, and treatment by bacteriophage of cholera reduced the mortality in two series from 55% and 70% to 23% and 21%. Specificity and potency are two essential features, and we find that a phage lysate to be effective must be active in at least a dilution of 1 in 1,000,000. One wonders, therefore, what has happened to the unfortunate typhoid cases whose mortality is reported stationary at approximately 20%. It is as easy to prepare rapidly really potent specific bacteriophage solutions to this group of organisms as to the dysenteries, so that one must reasonably look forward to a further paper from Dr. Compton reporting a similar significant drop in the mortality of the typhoid group in Alexandria.—I am, etc.,

London, W.1. HARRY COKE.

Obituary

DR. WILLIAM HENRY TURTON, who died at the end of April at the age of 79, had practised for many years at Heanor, Derbyshire, the town in which he was born. He studied medicine at the University of Edinburgh, graduating M.B., C.M. with first-class honours in 1886. He then began practice in Market Street, Heanor, and served for 54 years as medical officer of health for the Urban District, a post in which he is succeeded by his son Dr. Philip H. Turton. In every department of the town's life Dr. W. H. Turton used his knowledge and influence wisely and won the affection and respect of the whole neighbourhood. He was a man of many-sided tastes, with a deep interest in geology and zoology, on which he gave many public lectures. In Freemasonry he attained high honours. He had been a Justice of the Peace since 1916, and for some years deputy chairman of the Heanor Bench; he had also been warden of the Parish Church. In 1888 he began to take an active and prominent part in the work of the St. John Ambulance Association, becoming divisional surgeon and superintendent of the Heanor Ambulance Division, and afterwards county surgeon for the No. 5 District. He was appointed an officer of the Order of St. John after 32 years' service, and in 1935 was promoted to the rank of Commander of the Order. During nearly half a century of ambulance work he trained hundreds of candidates in first aid and left a lasting mark upon the efficiency of the district. Dr. Turton had been a member of the B.M.A. since 1912.

We regret to announce the death of Dr. WILLIAM GIBSON PARKER of Taunton, who was for many years assistant school medical officer under the Somerset County Council. He was born at Newcastle-upon-Tyne on July 30, 1878, the eldest son of the Rev. I. Parker, and was educated first at Wesley College, Sheffield; then at the Glasgow High School, and afterwards at the University of Birmingham and Guy's Hospital. He graduated M.B.Lond. in 1901 and took the Cambridge D.P.H. some years later. His early appointments were assistant house-surgeon at Guy's and assistant medical officer to the City Fever Hospital, Birmingham; then for a year he was medical superintendent at the Birmingham City Smallpox Hospital. Dr. Parker joined the British Medical Association in 1905, was honorary secretary of the West Somerset Branch 1924-7, and president in 1930-1. During the last war he served in the R.A.M.C. with the temporary rank of captain.

Dr. Bernard Leggett writes: I read with the greatest regret the obituary notice of Mr. GEORGE HUDDY, M.S., F.R.C.S. I was a student at the London Hospital when Mr. Huddy was registrar. At that time the manner of a few house-surgeons, registrars, etc., whose experience of life was bounded by hospital medical experience only, was on some occasions very irksome. Huddy was the opposite and showed to all an unfailing kindness and courtesy. Among my contemporaries he was greatly liked and appreciated, and the dresser or clerk who sought information from him would be treated with unfailing consideration and nothing was a trouble to him. Having attained the highest surgical distinctions, a future as a chief on "the London" appeared assured until he went to the Provinces, where first-class surgeons were becoming more in demand.

---

[1] Hamilton Bailey's work; appendix at back.

Universities and Colleges

UNIVERSITY OF CAMBRIDGE

The following candidates have been approved at the examination indicated:

FINAL M.B.—*Part I (Surgery, Midwifery, and Gynaecology)* J N. Agate, R J Alcock, W B Alexander, A G S Bailey, A D Barlow, H W A Baron, D. J. Bauer, A. O Bech, C P. Bennett, N L. Birkett, F. W Blacklay, R. J K Brown, P H Buxton, T. O Candler, A. W. Capon, E F Carr, F S. Carter, J M Childs, J. A H Collyns, D J. Conway, W. N Coombes, P N. Cunliffe, A J Danby, I N Darbyshire, J Dean, P J R. Deller, W. K. Douglas, M P Durham, P F Early, A G. Eddison, W F Felton, J. H. L Ferguson, J. L Fluker, T R Gilchrist, J V. T Gostling, A. G Harrold, P L. M. Hartley, D Hilson, T. S Hindle, R F Hollick S. C. H. Hood, P. H. S Hooper, E N M Johnston, H R. Jolly, L G Kingdom, W S S Ladell, F M Lancaster, F K Lau, T L. T Lewis, D I. Lishman, G C Lloyd Roberts, J Lomas, T G E Loosemore, D McAnally, I. M. MacArthur, E. L McDonald, N M Mann, H E. S Marshall, P H. N Matthews, R M S. Matthews, H R. A Michelmore, P A. G Monro, W K. S Moore, J. M. Morgan, Y. H Ng, W. J L. Pain, J. S. Pegum, J A Peters, R V. Peters, H L. Pierce, R J F H Pinsent, B Pownall, E Pringle, S H Purser, J F. P Quinton, R. K. Reid, W. Rogers, L. A Rook, H M. J. Rowan, I. A. Roxburgh, P H Sanderson, D L Sandes, O. L S Scott, T. O Scudamore, J. H Simpson, I. M Smith, O Sookias, J. W Squire, J H Steeds, J. P Stephens, H C. Still, J R Thompson, R. N Ticehurst, W. H Trethowan, G. S Udall, C. R. M Warner, D J Watt, L. A S White, E N Whitley, D. E. C Whittome, H I Winner. *Women:* F H Lomax, A. B. Willcock.

UNIVERSITY OF LONDON

In a report on the work of the University of London the Acting Principal, Mr. Harold Claughton, states that the medical students in 1940-1 were nearly 90% of the number for 1938-9, whereas non-medical students were only 56%. The proportion of men to women in the medical schools is 90%, again contrasting with the non-medical schools, in which the sexes now are about equal. The dispersal of medical schools, with the clinical students distributed throughout sector hospitals in the Greater London area, has had its compensations in the more varied experience of the students and their greater opportunity for practical clinical work. Reference is made to the offer of the Rockefeller Foundation, made to Universities of the United Kingdom in general, of a number of studentships to permit students to follow a two-year course in medical schools in the United States and Canada. Six London students have been awarded such studentships, and, to avoid a technical interruption of their courses of study, the schools to which they have been sent have been recognized by the University for the purposes of the M.B., B.S. examination. The chair in radiology at Middlesex Hospital Medical School, which was instituted twenty years ago but to which no one has ever been appointed, is now to be filled. Regret is expressed at the postponement, owing to the war, of many university developments. This year four great buildings would have been opened, including the ceremonial hall.

ROYAL COLLEGE OF SURGEONS OF ENGLAND

At a meeting of Council on June 11, with Sir Alfred Webb-Johnson, President, in the chair, the award of the Blane Medal to Surgeon Commander E. R. P. Williams, R.N., for his original work "A Hunterian Lecture on Blast Effects in Warfare" was announced. A report was made of the election as Hunterian Trustees of Lord Moyne, Sir Cuthbert Wallace, and Sir Hugh Lett. Surgeon Rear-Admiral C. P. G. Wakeley was appointed representative of the College on the Court of the University of Bristol and Mr. Ernest Finch was appointed representative on the Court of Governors of the University of Sheffield. The Hallett Prize, granted on the result of the Primary Examination for the Fellowship, was awarded to Miss Margaret Ruth Taylor of Manchester University. Examiners were elected for the ensuing year

Diplomas of Fellowship were granted to the following candidates S. G French, G. N. St. J. Hallett, H. N. G. Hudson, A J. Wilson, H. A. C. Chalmers, A. N. Guthkelch, T. W. Rowntree, J. H Hicks, J M. Fitton, W I. Cawkwell, M. Gamal-el-Din, C. R. Salsbury, A. B Watson, S. C. Williams.

Diplomas of Membership were granted to Janet W. Shrimpton and F. R Wilde

Diplomas in Anaesthetics were granted, jointly with the Royal College of Physicians of London, to the following candidates: Helen M. B. Alcock, R. E. Angel, T. H. Baillie, E. J. W. Barnard, J R. J Beddard, Stella G. Braithwaite, T. R. M. Bristow, A. Coleman, Florence K. Costello, J. P. Cuddigan, J H. Dixon, J D. Ebsworth, Phyllis M. Edwards, A. J. Evans, Mita Frost, Edith Gilchrist, G. P. Goodwin, J. R. Hindmarsh, A. R Hunter, Jean E. W. Inglis, Edith S. M. Merry, R. E. J. Pembrey, S. F. Polley, Norah K. Priestley, H. J. Richards, G K T. Roche, G F. Smith, A. E. Ward, F. Widlake, Gertrude A. Willis.

The Services

The A.F.C. has been awarded to Air Commodore P. C. Livingston, O.B.E., Acting Wing Commander R. H. Winfield, and Acting Squadron Leader E. B. Bright, R.A.F.

The Efficiency Decoration of the Territorial Army has been awarded to Lieut.-Col. G. P. Crowden, Major (Temp. Lieut.-Col.) D. L. Kerr, and Major C. E. Fenton, R.A.M.C., T.A.

The name of Acting Col. C. V. Thornton, M.C., R.A.M.C. (Reserve of Officers), attached to the Southern Rhodesia Medical Corps, has been mentioned in recognition of gallant and distinguished services in the Middle East.

The following officers have been mentioned in dispatches by Air Officers Commanding-in-Chief: Acting Group Capt. J. G. Russell, R.A.F.; Wing Commander D. H. Brinton, R.A.F.V.R., and Wing Commander J. H. Williams, A.A.F.; Squadron Leader C. W. S. Marris, R.A.F., and Acting Squadron Leaders F. R. Buckler, R. Carpenter, D. A. Davies, D. C. Farquharson, G. R. Gunn, S. J. Hadfield, and D. St. C. L. Henderson, R.A.F.V.R.; and Flight Lieut. J. N. Loring, R.A.F.V.R.

The King has approved the award of the George Medal to Acting Squadron Leader Robert Hill, R.A.F.V.R., Acting Flight Lieut. E. L. Williams, Leading Aircraftman C. J. Boarman, and Leading Aircraftman H. Sumray. The citation in a *Supplement* to the *London Gazette* dated June 8 reads as follows:

"One night in March, 1942, two aircraft, carrying bombs, collided on an aerodrome in Malta and burst into flames. Squadron Leader Hill (the station medical officer), Flight Lieut. Williams, and Leading Aircraftmen Boarman and Sumray immediately proceeded to the scene. Shortly afterwards the bombs began to explode and enemy aircraft began to bomb the area. Despite the great danger, Squadron Leader Hill, assisted by Flight Lieut. Williams and the two airmen, successfully extricated four members of the crews from the wreckage The prompt and gallant action of these officers and airmen undoubtedly saved the four lives. Squadron Leader Hill has invariably performed exemplary work in dealing with casualties during heavy bombing raids, and both he and Flight Lieut. Williams have set a magnificent example which has done much to maintain a high standard of morale on the station. The bravery shown by Leading Aircraftmen Boarman and Sumray has been an inspiration to others."

CASUALTIES IN THE MEDICAL SERVICES

Surg. Capt. ALGERNON EDGAR PERCY CHEESMAN, R.N., who is included as killed in an Admiralty Casualty List published on June 10, received his professional education at Guy's Hospital and qualified M.R.C.S., L.R.C.P. in 1909. He held a house appointment at Leicester Infirmary before entering the Royal Navy as surg. lieut in 1910. He was promoted surg. lieut.-cmdr. in 1921, surg. cmdr. in 1923, and was placed on the retired list in March, 1941, with the rank of surg. capt., but was re-employed for service during the present war. He had been a member of the B.M.A. since 1931.

Surg. Cmdr. DOUGLAS ARNOLD NEWBERY, R.N., who was reported missing in Dec., 1941, is now presumed to have been killed in H.M.S. *Repulse* on Dec. 10, 1941. He received his professional education at Guy's Hospital, qualified M.R.C.S., L.R.C.P. in 1926, and immediately entered the Royal Navy as surg. lieut., being promoted surg. lieut.-cmdr. in 1932 and surg. cmdr. in 1938. In Sept., 1926, he was appointed to the flotilla leader *Keppel*, for duty with the destroyers of the 3rd Flotilla; in 1929 he joined H.M.S. *Iron Duke*; and from 1930 to 1933 he was stationed at Gibraltar Dockyard. After further service afloat in H.M.S. *Renown* and H.M.S. *Terror* he was employed at Haslar Hospital from 1934 to 1937, when he was appointed to H.M.S. *Sussex*. He leaves a widow. He had been a member of the B.M.A. for 10 years.

Surg. Cmdr. THOMAS CLOVER LARKWORTHY, R.N.V.R., who is now officially presumed killed in H M.S. *Neptune*, was 38 years of age, the son of Mr. and Mrs G. Larkworthy. He graduated B.A. at Cambridge in 1924 and qualified M.R.C.S., L.R.C P. in 1928, proceeding M.A. in the same year, also taking the B.Chir. degree in 1932 and the M.B. in 1937. He had been house-physician at the Brompton Hospital, resident obstetrical assistant, house-surgeon, house-physician, and casualty officer at St. George's Hospital, and clinical assistant at the Hospital for Women, Soho Square. At the outbreak of war he was senior clinical assistant at Brompton, and clinical assistant at the Victoria Hospital for Children and the infant welfare department of St. George's. He entered the R.N.V.R. before the war and in Sept., 1939, held the rank of surg. lieut.-

cmdr., being called up for service in December of that year. On Jan. 1, 1941, he was promoted to acting surg. cmdr. and was mentioned in dispatches. He leaves a widow.

Surg. Lieut.-Cmdr. HAROLD THEODORE LOGAN BROADWAY, R.N.V.R., is posted as missing, presumed killed in an Admiralty Casualty List published on June 24. He received his professional education at St. Thomas's Hospital, qualified M.R.C.S., L.R.C.P. in 1932, and then held the house post at the Royal Victoria and West Hants Hospital, Boscombe. He had been in practice in Dorchester since 1932, in partnership with Dr. T. B. Broadway, and was honorary anaesthetist to the Dorset County Hospital. He entered the R.N.V.R. as temp. prob. surg. lieut. soon after the outbreak of war and was reported missing in the *Journal* of March 21. He had been a member of the B.M.A. since qualification.

Surg. Lieut. JOHN WENLOCK ASHLEY, R.N.V.R., the elder son of Mr. and Mrs. L. Ashley of Tenbury, Worcestershire, is reported missing, presumed killed on active service last month. He was born on Sept. 27, 1914, and was educated at the University of Oxford, where he graduated B.M., B.Ch. in 1939. He entered the R.N.V.R. soon after the outbreak of war and was injured while serving in a destroyer in 1940. He had also seen service in H.M.S. *Hermione.*

Surg. Lieut. JAMES FREDERICK NEWMAN, R.N.V.R., who was reported missing in the *Journal* of Sept. 21, 1940, is now presumed to have been killed on active service when his ship, H.M.S. *Esk*, was sunk in the North Sea by enemy action in Sept., 1940. He was born on May 1, 1914, and was educated at Wycliffe College and the University of Birmingham, where he graduated M.B., Ch.B. in 1938. He had held house posts at the Staffordshire General Infirmary. In March, 1939, he entered the Supplementary Reserve of the R.N.V.R., and when war broke out he was mobilized with the rank of temp. surg. lieut., and saw service at the first Battle of Narvik and at the Dunkirk evacuation. He leaves a widow, Dr. Joan J. Newman, who is a member of the medical profession and who was his fellow student.

Wounded or Injured.—Prob. Temp. Surg. Lieut. R. P. M. Miles, R.N.V.R.

Missing.—Squadron Leader J. A. MacCarthy, R.A.F., Capt. C. Rigby, R.A.M.C., Lieut. E. Snell, R.A.M.C.

Prisoners of War.—Lieut. G. D. Cribb, R.A.M.C., Lieut. H. Rosenberg, R.A.M.C.

Medical Notes in Parliament

Health and Training of Youth

On June 16 the House of Commons considered the education estimates. Mr. BUTLER, President of the Board of Education, said that there was a substantial rise in the expenditure on education this year due, in part, to increased provision for meals and milk. The sum set aside for the youth service had also increased from £136,000 to £250,000. Over 700,000 children now took their midday meals at school. Last year 1,733 proposals providing for 240,000 children were approved, and from January to May of this year the number sanctioned was 3,642, providing for over half a million children. He saw no reason now why the target already mentioned of one million meals a day for children should not be reached by the end of the summer. He had consulted his medical advisers before making the statement that he believed the health of the children—largely thanks to these proposals and to the fact that some 3,250,000 children were now getting milk at school—had positively improved and that in wartime. It had been decided to extend to all schools the benefits of the milk-in-schools scheme, now confined to grant-aided schools. The result would be that all school children would be able to get milk for drinking at the price of ½d. per one-third of a pint.

With regard to the school medical and dental services, the volume of treatment given to school children in 1941 was almost as great as in 1940 and the years immediately preceding the war. That was not to say that everything was all right. The loss of doctors to the Services had been very severe, but the Board was doing its best to meet the situation. The Board had stimulated the formation of new nursery classes and play centres to look after the children of women engaged in war work, and for this purpose a new department had been established in Kingsway. He was determined that the educational value of the wartime nurseries should find full scope. Perhaps a more direct contribution by the schools to the war effort was the steady flow of qualified recruits for the Services which came from the secondary schools. The technical colleges all over the country had been given over very largely to the training of expert personnel for the Services.

Youth Advisory Council

Referring to the youth service, he said that every authority for higher education now had a youth committee and a substantial number of local organizers had been appointed. To help in the growth and expansion of the movement, he had felt the need for some closer contact with those connected with the actual work, and he proposed accordingly to appoint a Youth Advisory Council. This council was the first attempt to include in one body many types working among our youth—administrators, members of youth committees, and younger people engaged in this work, whether in voluntary or pre-Service organizations. One member was a chairman of a Juvenile Court, and there would be those who could speak with knowledge of the employer's and employee's point of view. The chairman would be Mr. Wolfenden, headmaster of Uppingham. The great mass of children broke off their education suddenly at about the age of 14, Parliament voted millions in the estimates, and then ceased to exercise a continued care and supervision over adolescents. This loss would not be obviated merely by raising the age for full-time schooling to 15 or even to 16, though we should take the former step when we got the chance. The new registration scheme had already recognized that up to at least 18 young people should be regarded as still falling within the province of the education service. He hoped the Youth Advisory Council would be an advance along the road to a more integrated national service for youth. To do what was right by the health and the welfare of the young people not only was continued supervision necessary, but the young people must be treated as learners and not simply as earners in their first years in employment. In the interests of youth, as well as out of consideration for our future industrial and commercial welfare, the time had come to review the whole system of industrial and commercial training, including the apprenticeship systems.

After debate, the discussion on the estimates was adjourned

Committee on Child Welfare

Mr. ERNEST BROWN told Miss Rathbone on June 11 that an advisory committee on the welfare of young children had been constituted. He would act as chairman, with Miss Horsbrugh as vice-chairman. The committee would advise him on any question affecting the welfare of expectant and nursing mothers and of children under 5 which are referred to it. It would do most of its detailed work through subcommittees appointed for the investigation of particular problems. The medical members of the Committee are Dr. Ethel Cassie, Dr. Letitia Fairfield, Dr. Dennis Geffen, Dr. William S. Macdonald, Dr. Alan Moncrieff, Dr. Annie Rowlands, Dr. Charles M. Smith, Mr. Arnold Walker, and Dr. Edith Williamson.

Period of Clinical Studies

On June 11 Sir E. GRAHAM-LITTLE asked Mr. Brown to address simultaneously and in the same terms his request, now sanctioned by the General Medical Council, to all the medical licensing bodies in Great Britain so as to avoid the inequality of sacrifice which must result from sporadic action on the part of individual licensing bodies. Mr. BROWN said the General Medical Council had communicated on this question with all licensing bodies and examining boards in Great Britain and Northern Ireland.

Psychoneuroses and Pensions

Replying on June 11 to Lieut.-Comdr. Hutchison, Sir WALTER WOMERSLEY said the grant of pension for any disability, including psychoneurosis, depended on whether the condition was accepted as attributable to or materially aggravated by service. It could not be assumed that a disability could be so accepted simply because it led to discharge from the Service. The question must be determined in each case in the light of the nature of the disability and the service and medical history of the claimant. Provision was made by the Ministry of Pensions for the treatment in special neurological centres under the E.M.S. of men discharged from the Services suffering from a condition of neurosis, provided they were likely to benefit by such treatment. This treatment was granted whether the condition was accepted by the Ministry or not.

Maternity Beds in Scotland

On June 16 Mr. JOHNSTON told Dr. Summerskill that 42 of the 55 Scottish local authorities with power to provide maternity beds had done so either in special maternity hospitals, of which there were 22 with 555 beds, or in general hospitals, where there were 400 maternity beds. There were also in Scotland 700 maternity beds in voluntary hospitals, and 300 beds in 10 maternity hospitals provided by the Government for expectant mothers who had been evacuated, but which in practice were also used for other patients. There was, therefore, a total provision of nearly 2,000 maternity beds in the country. Local authorities did not specifically allocate beds as free ones; they charged according to the patients' means, and in necessitous cases no charge was made.

Eye Injuries in Ordnance Factories

On June 17 Sir **Andrew Duncan** told Sir Francis Fremantle that returns of eye injuries at Royal Ordnance Factories had not hitherto been abstracted from case records, but arrangements had now been made to obtain these returns. Adequate preventive measures were taken by the provision of guards or goggles where necessary. Minor injuries were treated at the factory surgery, but where the injury was serious the employee was sent to hospital.

Silicosis Disablement

On June 16 Mr. **Ness Edwards** asked the Home Secretary the number of claims for silicosis certificates made by South Wales coal-miners to the Medical (Silicosis) Board. Mr. **Peake** said that 658 applications for disablement certificates were made in 1939, of which 271 were refused; in 1940, 825 were made and 396 refused; and in 1941, out of 1,136 applications, 662 were refused.

Civilian Medical Services

Mr. **Duncan Sandys**, answering Mr. T. E. Harvey on June 18, said the allocation of doctors for the needs of the fighting Services, in relation to those of the civilian population, was based on a careful system of priorities worked out by the Medical Personnel Priority Committee set up by the Minister of Health, the Secretary of State for Scotland, and the three Service Ministers. Many medical officers had already been granted temporary release from the Army to meet civilian needs. This practice had been in force for over twelve months and the War Office would maintain it as fully as the needs of the Service allowed.

Mr. **Brown** announced on June 18 that the Secretary of State for War had agreed in principle to the temporary loan to understaffed civilian hospitals of Army nurses who could be spared. Details were under discussion. There was a standing arrangement under which Army doctors would give all possible assistance to a civil hospital if required in an emergency. Medical Personnel Priority Committees in each Region had constantly under review the co-ordination of military and civil hospital services.

Mr **Ivor Thomas**, on the same date, asked Mr. Brown to undertake that, before any more general practitioners were released for the Services, the E.M.S. would be reduced to a size more comparable with proved needs. Mr. **Brown** answered that a percentage reduction in the whole-time medical staffs of hospitals, including those enrolled in the E.M.S., was already being carried out in the light of the proved needs of the hospitals. In addition, the period for which hospital appointments might be held by recently qualified doctors liable to military service had been restricted. The reduction of hospital staffs was, therefore, proceeding concurrently with the call for more general practitioners for the Services.

Family Allowances

On a motion by Wing Commander Wright, in the House of Commons on June 23, commending for the Government's consideration a national scheme of allowances for dependent children, Sir **Kingsley Wood** said that even if the principle of family allowances was accepted there were a number of important matters which still remained to be decided: whether such a scheme should be contributory or non-contributory; whether its benefits should be extended to families of all incomes or be confined to the poorer ones; whether it should be confined to the larger families by excluding the first eligible child or the first two eligible children in each family. There were also much wider and more important considerations about the effect of family allowances on the present wartime economy, particularly if given on a large scale and paid in cash If the motion were adopted, the Government would give full consideration to the matter in the light of the Beveridge report, the further conclusions of organized labour, and the financial position. It should be possible for all these matters adequately to be considered in the autumn. They would be given immediate attention, conclusions would be reached as rapidly as possible and communicated to the House, when, no doubt, there would be occasion for further discussion.

Medico-Legal

A FATAL OVERDOSE OF CARBACHOL

Carbachol became official in the Third Addendum to the *British Pharmacopoeia, 1932.* Chemically it is carbamylcholine chloride, the urethane of choline. It is sold in this country under the proprietary names of "moryl" and "choryl." A foreign proprietary of similar composition was formerly marketed here under the registered name "doryl." Carbachol is officially described as consisting of "small, colourless, hard, prismatic crystals, or a crystalline powder." The dose by mouth is 0.001 to 0.004 g. and by subcutaneous injection 0.00025 to 0.0005 g. It is soluble in equal parts of water. The effects are like those of acetylcholine—that is to say, it is a powerful vasodilator and cardiac depressant. Carbachol stimulates the parasympathetic nervous system. It causes contraction of the intestinal and bladder muscle, and is used subcutaneously or intramuscularly to relieve post-operative intestinal atony and promote micturition due to atony of the bladder wall. Its action by the mouth is less certain than by injection. In comparison with acetylcholine the effects on the gastro-intestinal tract and the bladder appear to be greater, and those on the cardiovascular system less (F. R. Fraser, *Journal,* 1938, **1**, 1293). Its great value is in the relief of urinary retention not due to obstruction.

The *Oxford Mail* of June 4 printed a full report of an inquest held by the city coroner, sitting with a jury, on Flight-Sergeant J. Simpson, R.A.F., aged 41, who died in the E.M.S. department of the Cowley Road Hospital after an overdose of "moryl." The charge-sister said that on May 11 a representative of a local firm of chemists called as usual on his daily visit, and among other things she ordered ampoules of "moryl," but did not indicate any specified form. She expected it to be supplied as a liquid, with which form she was familiar. She opened the box on May 19 for the purpose of giving an injection to Sergeant Simpson on the instructions of Dr. Lovas. She noticed that the drug was in crystals and was a little surprised not to find it in liquid form, though she had seen the crystal type a few days before when another sister had asked for some "moryl" out of her store. She dissolved the crystals in the ampoule in sterilized water and gave the injection at 11.50 a.m. She did not then know that the dosage of one ampoule applied only to liquid "moryl" and not to crystal "moryl." There were no instructions on the box stating that crystal "moryl" was not to be used for injection. Another sister gave evidence that a nurse whom she had sent to watch Sergeant Simpson immediately after the injection while she herself served dinner reported that he was breathing strangely. She found him almost pulseless, very blue, gasping, and in a collapsed condition. She sent for the doctor and started applying oxygen, but the patient died at 12.5 p.m. before the doctor's arrival. The manager of the branch pharmacy gave formal evidence of receipt and delivery of the drug. He did not know that "moryl" was done up in both liquid and crystal form. When he ordered the drug from Savory and Moore's Oxford establishment by telephone he was not asked if he required it in liquid, crystal, or tablet form. Evidence was then given regarding a patient in the same hospital who had an ampoule of "moryl" on April 9, and collapsed, but recovered after oxygen; and another patient, who had had an ampoule of liquid "moryl" without ill effect on May 9, but collapsed after administration of an ampoule of crystal "moryl" dissolved in water on May 10 and recovered from this under treatment. In reply to the coroner the sister said that she expected that one ampoule of crystals dissolved in sterilized water would be the same as one ampoule of liquid "moryl." The factory manager of Savory and Moore's said that boxes of "moryl" in crystal form were sometimes sent out with instructions and sometimes without. The general practice with hypodermic injections was not to issue any instructions as to the way they were to be injected. His firm had been making "moryl" for two years and there had been no previous complaint about its use. Dr. A. Lovas, a medical graduate of Prague serving in the E.M.S. department at the hospital, said that on the day after the operation on Simpson for haemorrhoids he gave instructions for an injection of one ampoule of "moryl" to be given. Several months earlier he had read the instructions given on a box of ampoules of liquid "moryl," and being unaware that "moryl" was supplied in crystal form he thought it sufficient to give instructions for a patient to have one ampoule of "moryl." If he had known that in two earlier cases of collapse crystals had been used instead of liquid, that would certainly have put him on inquiry. Dr A. H. T. Robb-Smith, director of pathology at the Radcliffe Infirmary, who had conducted a post-mortem examination, gave the opinion that death was caused by an overdose of the drug. The jury returned a verdict of death due to an overdose of "moryl" accidentally given, and added a rider: "We consider that the method of handling the drug at the hospital and the manner of labelling the drug by the manufacturers are both deserving of censure."

EPIDEMIOLOGICAL NOTES

Discussion of Table

In *England and Wales* during the week there was a rise in the notifications of whooping-cough 213, diphtheria 54, and cerebrospinal fever 13: and a fall in measles 624, acute pneumonia 107, dysentery 45, and scarlet fever 33. The largest rises in the incidence of whooping-cough were in Warwickshire and London, where 51 and 41 cases more than in the preceding week were notified.

Diphtheria, with a rise of 54, due to the experience of Wales and Northern England, reached almost the level of the last three weeks in May. The lower incidence of measles was more pronounced than last week, although the decline was not general throughout the country. The largest decreases were those of London and Surrey, 157 and 140 less than the totals of the preceding week. The high level of incidence in Kent and Lancashire remained unchanged, whilst the notifications in Durham rose by 51. The lower incidence of scarlet fever was mainly due to the experience of London and of Wales. In Yorks West Riding and Kent there was a slight increase in notifications. Eleven more cases of dysentery were reported from Yorks West Riding, Wortley R.D., and this was the only outbreak of any note during the week.

In *Scotland* a fall in the incidence of infectious diseases was reported, dysentery, with an increase of 9 cases, being the only exception; 714 cases of measles, 186 fewer than in the preceding week, were notified in Glasgow.

In *Northern Ireland*, in Belfast, the notifications of measles numbered 342, a decrease of 26, but as only the first case in a household has to be notified, unless two months intervene between cases, the actual number is probably larger.

Quarterly Return of the Registrar-General for Scotland

The report for the first quarter of 1942 shows that Scotland enjoyed a very favourable mortality experience, particularly from infectious diseases. The marriage rate of 10.3 per 1,000 was the highest ever recorded for any first quarter in Scotland.

Live births numbered 21,881 and corresponded to a rate of 17.7 per 1,000 of the population, which was 0.1 below the average for the March quarter for the five years 1937-41. The illegitimate births were 7.0% of the total and were 1.0 above the average. The infant mortality rate—90 per 1,000 live births—was an improvement on previous experience. This rate was 19 below that for the first quarter of 1941 and 7 below the five-year average. Maternal mortality was 5.3 per 1,000 live births—an increase of 0.4 on the average of the preceding five years for the first quarter.

19,441 deaths were registered during the quarter, equivalent to a rate of 15.7 per 1,000 of the population. This rate was 3.2 below that recorded in the corresponding quarter of 1941 and 1.8 below the five-year average. There were only 411 deaths from the principal epidemic diseases—about one-third of the number recorded in the first quarter of 1940. The death rate from these causes was 33 per 100,000 of the population—about one-quarter of the five years' average rate for the March quarter. The death rates for all forms of tuberculosis were 57 per 100,000 and 67 for respiratory tuberculosis; these rates showed practically no change from the five-year average. Despite the severity of the winter the death rate for both bronchitis and pneumonia was only 89 for each cause as compared with 130 and 135 respectively, the average rate for the first quarters of the five preceding years.

Returns for the Week Ending June 20

The notifications in England and Wales during the week included the following numbers: scarlet fever 1,317, whooping-cough 1,389, diphtheria 660, measles 6,629, acute pneumonia 593, cerebrospinal fever 104, dysentery 71, paratyphoid 9, typhoid 7.

Outbreak of Small-pox

According to statements in the Press there have been up to date 22 cases of small-pox in Glasgow. Of 7 patients from a ship 2 have died; 4 cases of small-pox have also been reported in the Swindon area.

No. 23

INFECTIOUS DISEASES AND VITAL STATISTICS

We print below a summary of Infectious Diseases and Vital Statistics in the British Isles during the week ended June 13.

Figures of Principal Notifiable Diseases for the week and those for the corresponding week last year, for: (a) England and Wales (London included). (b) London (administrative county). (c) Scotland. (d) Eire. (e) Northern Ireland.

Figures of Births and Deaths, and of Deaths recorded under each infectious disease, are for (a) The 126 great towns in England and Wales (including London). (b) London (administrative county) (c) The 16 principal towns in Scotland. (d) The 13 principal towns in Eire. (e) The 10 principal towns in Northern Ireland.

A dash — denotes no cases; a blank space denotes disease not notifiable or no return available.

† Owing to evacuation schemes and other movements of population, birth and death rates for Northern Ireland are no longer available.

UNIVERSITY COLLEGE OF MEDICINE LIBRARY

Medical News

Prof. Major Greenwood, F.R.C.P., F.R.S., will give a public lecture on "Civilian Hazard of Life in this War and in the Last: A Profit and Loss Account for 1915-16 and 1940-1" at the London School of Hygiene, Gower Street, W.C., on Thursday, July 16, at 2.30 p.m.

The thirty-first Long Fox Memorial Lecture will be delivered in the Lecture Theatre of the H. H. Wills Physics Laboratory (Royal Fort), University of Bristol, on Tuesday, July 7, at 8.30 p.m., by Prof. C. M. Yonge, D.Sc., whose subject is "The Experimental Study of Development."

The London and Home Counties branch of the Child Health Planning Group will hold its inaugural meeting at 13, Hill Street, Berkeley Square (British Dental Association headquarters), on Saturday, July 18, at 2.30 p.m.

The name of Col. Robert Bruce, D.S.O., M.D., Deputy Lieutenant for the County of Aberdeen and chairman of the Territorial Army Association for the County of Aberdeen, was omitted from the list of Birthday Honours published in the *Journal* of June 20. He received the C.B. (Civil Division).

The Heberden Society has awarded the Heberden Medal for Research in Rheumatic Diseases for 1942 to Dr. Philip S. Hench of the Mayo Clinic, Rochester, Minnesota, in recognition of his distinguished contributions to the subject over a number of years, and particularly of his most recent work on the effect of jaundice on the course of rheumatoid arthritis.

The 89th annual general meeting of the Governors of Epsom College was held on June 19 at 49, Bedford Square, London, W.C. In moving the adoption of the Council's report, Lord Leverhulme, the President, congratulated the Treasurer, Council, headmaster, and bursar for the way in which they had tackled the burdens of an exceptionally difficult year, which showed a reduction in numbers and a financial loss. The report was unanimously adopted, and the Governors received the announcement of Foundation scholarships, pensions, and educational grants awarded by the Conjoint Committee in May.

The Queen has allocated £2,000 from the "Bundles for Britain" Fund to the Belfast Hospital for Sick Children towards the establishment of a child guidance clinic.

Letters, Notes, and Answers

All communications in regard to editorial business should be addressed to THE EDITOR, BRITISH MEDICAL JOURNAL, B.M.A. HOUSE, TAVISTOCK SQUARE, LONDON, W.C.1.

ORIGINAL ARTICLES AND LETTERS forwarded for publication are understood to be offered to the *British Medical Journal* alone unless the contrary be stated.

Authors desiring REPRINTS should communicate with the Secretary of the Journal Board, B.M.A. House, Tavistock Square, W.C.1, on receipt of proofs. Authors over-seas should indicate on MSS. if reprints are required, as proofs are not sent abroad.

ADVERTISEMENTS should be addressed to the Advertisement Manager (hours 9 a.m. to 5 p.m.). Orders for copies of the *Journal* and subscriptions should be sent to the Secretary.

TELEPHONE No.—B.M.A. and *B.M.J.*: EUSTON 2111.

TELEGRAPHIC ADDRESSES.—EDITOR, *Aitiology Westcent, London*; SECRETARY, *Medisecra Westcent, London*.

B.M.A. SCOTTISH OFFICE: 7, Drumsheugh Gardens, Edinburgh.

QUERIES AND ANSWERS

Coltsfoot

"TUSSILAGO" writes: Can any colleague put me wise about coltsfoot, said to be good for asthma? Should the leaves be young or mature? How are they cured? I read that coltsfoot was smoked before the arrival of tobacco in this country, and that Pliny advised that the smoke from the burning leaf be inhaled through a reed. Information about the manufacture would interest me.

Blood Slides in Heat Pyrexia

Wing Commander S. B. S. SMITH (R.A.F. Medical Branch) writes: I note that Surg. Lieut.-Cmdr. Corr in his article on treatment of heat pyrexia by lumbar puncture (June 20, p. 761) makes no mention of blood-slides being taken to exclude malaria. Hyperpyrexial malaria is not uncommon when high atmospheric temperature is combined with high humidity. Were blood slides taken at a later date, and if so with what result?

Income Tax

Assistant's Accommodation

D. S. pays his assistant a salary, etc., "and £113 allowance for rent and rates of a furnished house which he has taken." He understands that if he pays the rent himself the assistant would not have to account for tax on the £113; but could he (D. S.) continue to deduct that amount as a professional expense?

** The reply cannot be given in quite such simple terms. If D. S. had taken the furnished house and required the assistant to live in it, he could have deducted the £113 as a professional expense and the assistant would not have been liable to tax on it, as the benefit would not have been convertible by him into money. But as matters stand payment of the £113 is a monetary liability of the assistant, and if D. S. discharges that liability for him the effect is the same as if he had paid him that amount in cash. If the tenancy and service agreements are altered making D. S. the tenant and requiring the assistant to live in the house provided, the assistant will cease to be liable to tax on the £113 as from the effective date of the change, and D. S. will still be entitled to deduct that amount as a professional expense; but until such a change is made no difference in the legal position with regard to income tax would be created merely by the rent and rates of the premises being paid by D. S. instead of by the assistant.

LETTERS, NOTES, ETC.

A Family History of Intussusception

Mr. JOHN J. LISTON, honorary surgeon to the Royal Portsmouth Hospital, writes: In May this year I operated on Sylvia X, aged 4 months, for intussusception. It was of the ileo-caecal type and early. She was the 14th child of the family. The mother stated that several of her children had suffered from the condition previously. On inquiry the following history was obtained. Reginald X died after operation for intussusception; age and date not known as the records have been "blitzed." Leslie X, aged 9 months, died after operation on April 5, 1930, for intussusception. Kenneth X, operation for intussusception on July 30, 1939, aged 3 years, alive and well. Ronald X, operation for intussusception on March 3, 1933, aged 5 months. Again operated on for intussusception on July 7, 1933; alive and well. Sylvia X, case quoted above, alive and well.

Blood Groups in Nullity Suit: Correction

We regret the clerical error by which, in the note under this title which appeared in our issue of June 20, p. 776, the child's blood group was given as ABN instead of ABMN. The mistake did not contradict the double exclusion of the husband (OM) from paternity which was the outstanding feature of the case, but had the effect of also excluding the mother (BM).

MEDICINE 100 YEARS AGO

Extract from the *Provincial Medical Journal* of July 2, 1842:

"The peaceful but arduous labours of the medical man render peculiarly obnoxious to him the heart-burnings, jealousies, and strifes engendered by the present condition of medical affairs. To continue his way, quietly and respectably, in the exercise of his profession, benefiting mankind by his science, while he procures for himself and his family the means of honourable existence, is the main object of his ambition. To pursue this object in peace is impossible under the existing state of medical affairs. The conflicting interests of our rulers have entailed upon us the curse of the disobedient son; the hand of the medical man is incessantly raised against his brother; laws and regulations, with the enactment of which we have no concern, have created a diversity of interests in our community, and introduced confusion and strife into a commonwealth where harmony of feeling and identity of interests should have prevailed; the character of the medical man is thus lowered in his own eyes, while the public estimation which he enjoyed is deteriorated in a still greater degree. These facts are brought home to every member of the profession in all parts of the empire. At one time the demand for medical reform was but a low and confused murmur; it is now the voice of the many—strong in number, and confident in the justice of their cause. But what is the measure of reform which we ask?—what the amendment which the enemies of reform affect to represent as a destruction of ancient institutions, prompted by a vague and restless love of change? The majority of reformers—those with whom all prudent and true friends of the profession are prepared to act—require nothing very violent in action, or destructive in its effects; they simply ask, as a fundamental measure, the institution of an uniform qualification for all persons who shall hereafter enter the medical profession; and, as a necessary consequence, they demand an equality of privileges for all those who shall have thus obtained an uniform qualification."

MEGALOBLASTIC ANAEMIA OF PREGNANCY AND THE PUERPERIUM

BY

L. S. P. DAVIDSON, M.D., F.R.C.P.Ed.&Lond.

L. J. DAVIS, M.D., F.R.C.P.Ed., M.R.C.P.Lond.

AND

JAMES INNES, M.B., Ch.B., M.R.C.P.Ed.

(From the Department of Medicine, University of Edinburgh)

Apart from the apparent anaemia caused by physiological dilution of the corpuscles resulting from increased plasma volume in pregnancy (Dieckmann and Wegner, 1934) and the hypochromic anaemia due to nutritional iron deficiency which has been shown by Davidson, Fullerton, and Campbell (1935) to be of frequent occurrence in pregnant women of the poorer classes, it has been recognized since 1842 (Channing, 1842) that a severe anaemia of the pernicious type may complicate pregnancy. Very occasionally it is of the classical Addisonian type, having antedated the onset of pregnancy, but more often it is an anaemia closely resembling Addisonian pernicious anaemia which develops during the course of pregnancy. Osler (1919) discussed this latter condition and pointed out that it differed from Addisonian anaemia in that recovery, when it takes place, is permanent. It should be noted, however, that the number of cases upon which this observation was based was small and that the haematological data submitted were inadequate and unsatisfactory—for instance, two of the cases had a colour index of 0.6.

A number of cases of this type of anaemia have been recorded in temperate climates during the past 20 years, but most authors have stressed its rarity. Thus Evans (1929) states that not one case of macrocytic anaemia was observed in 4,000 pregnancies. Whitby (1932), Wilkinson (1932), Bethell (1936), and Musser (1940) all indicate that the condition is encountered but seldom. On the other hand, Stevenson (1938) during six years studied 30 cases in Glasgow, which she classified as "pernicious, megaloblastic, or hyperchromic anaemia of pregnancy or puerperium." It is significant to note, however, that of her 30 cases only 17 had a colour index above unity, and that Price-Jones curves showed a shift to the right in only 6 cases. Leucopenia was present in 8 cases only. She concluded, on the basis of the frequency with which polychromasia, nucleated red cells, and immature leucocytes were observed, that the blood pictures reflected greater activity of the bone marrow than is found in Addisonian pernicious anaemia in relapse, and that an added iron deficiency sometimes complicated the picture. No observations on the bone marrow were recorded by Stevenson or the other workers mentioned above. Another significant observation by Stevenson was that achlorhydria was uncommon, being present in only 3 of her 19 cases.

Investigation of 16 Cases

In Edinburgh during the past two years we have studied 16 cases of this type of anaemia referred to us by our obstetrical colleagues. During this period there were approximately 8,000 confinements in the maternity hospitals concerned, but as no special study of anaemia in pregnancy was being undertaken by us, and as the cases were seen only in the course of our routine work as hospital physicians, it is reasonable to assume that many additional cases occurred during the period under review. Seven of the cases were seen by us prior to the use of liver therapy, but in the remaining 9 cases treatment had been instituted from two days to two months before we were called into consultation on account of their refractoriness to treatment.

Age.—The ages of the patients are set forth in the Table. It will be noted that 9 were between 23 and 30, 5 were between 30 and 40, and 2 were aged 41. It is evident that the ages are considerably lower than those commonly met with in Addisonian pernicious anaemia.

Number of Pregnancies.—Two of the patients were primigravidae, 6 were primiparae, 4 were in their seventh, and 4 were in their third, fourth, sixth, and ninth pregnancies, respectively. It is commonly held that pernicious anaemia of pregnancy occurs mainly in women who have borne several children, but it will be seen that this is not supported by our experience.

History of Anaemia.—Only 2 of the patients were seen by us before delivery, but examination of case records revealed a history of marked pallor and dyspnoea during pregnancy in 13. In 8 of these cases haemoglobin figures were available, ranging from 18 to 52%, and more detailed haematological data available in 4 of them indicated a severe anaemia of the pernicious type. It was repeatedly noted that the anaemia became progressively more severe during the last two months of pregnancy.

Peripheral Blood Findings

The data recorded in the Table are those obtained when the patients were first seen by us. It has already been noted that liver therapy had previously been instituted for varying periods of time in 9 cases before they came under our observation.

The *red cell counts* are seen to vary from 0.57 to 3.2 millions per c.mm., being below 1.7 millions in 11 of the cases. *Haemoglobin concentrations* were estimated by the Haldane method, 100% being equivalent to 13.8 g. per 100 c cm. The figures ranged from 12 to 52%, being below 40% in 12 cases. Ten of the patients had *colour indices* above unity. It is generally agreed, however, that the normal range is from 0 9 to 1.09. On this basis the colour indices were greater than normal in only 6 cases, within normal limits in 8 cases, and below normal in 2. Of the 7 patients seen before beginning treatment, only 3 had colour indices above 1.09, while of the 5 seen within a week of beginning liver therapy 4 had colour indices within the normal range. In view of the short time that had elapsed since treatment of these latter patients had been started, we consider it improbable that they had

4253

previously displayed high colour indices. Of the 2 hypochromic cases, one (No. 9) was an unusual case, to which further reference will be made, while the blood picture of the other (No. 8) was modified by a blood transfusion given shortly before the recorded blood examination was made by us.

Anisocytosis and ovality of outline of the red cells were not considered by us to be so prominent in these cases of anaemia of pregnancy as we have been accustomed to find in classical Addisonian anaemia of equivalent severity.

Macrocytosis.—Price-Jones curves were not constructed, but the films were carefully inspected with a view to assessing the approximate frequency of cells of different sizes. We feel that, with experience and using a constant magnification, a very fair approximation can be obtained by visual inspection. In 9 of the cases we noted numerous macrocytes, and formed the opinion that the mean cell size was greater than normal, while in 7 the mean cell size did not appear to exceed normal limits.

Leucocytes.—In 9 patients the white cell counts were within or below normal limits. A leucocytosis was present in 4, all of whom were suffering from septic complications.

Table showing Details of 16 Cases of Megaloblastic Anaemia of Pregnancy

GROUP I.—CASES DISPLAYING A PROMPT RESPONSE TO LIVER THERAPY

* Sternal marrow examined two weeks after beginning of response to liver therapy.

Other Findings

Sternal Marrow.—Sternal puncture was performed in 13 of the cases. The resulting films with one exception showed numerous primitive megaloblasts. In 6 of the 7 cases seen before beginning liver therapy the qualitative and quantitative erythroblast pictures were identical with those found in Addisonian pernicious anaemia in the stage of relapse. The remaining marrow film, from Case 9, contained many megaloblasts, but the normoblasts were more numerous than we should expect to find in a case of Addisonian pernicious anaemia at the level of 3.2 million erythrocytes per c.mm. The marrow films from the cases seen subsequent to starting liver injections presented the mixed megaloblastic and normoblastic pictures that have been previously described by us in Addisonian pernicious anaemia responding to treatment (Davidson, Davis, and Innes, 1942). The bone marrow in Case 13, which gave a normoblastic picture, was examined two weeks after a response to liver therapy had occurred.

Gastric Juice.—It was practicable to carry out gastric analysis in only 11 of our cases when they were first seen. Free hydrochloric acid was present in 7. In the course of subsequent examinations free hydrochloric acid was found in 3 of the cases that had not been tested previously. Thus of 14 cases tested only 4 were found to have a histamine-fast achlorhydria.

Sepsis.—Septic complications developed during the puerperium in 9 cases. The conditions were: mastitis in 4 cases, pyelitis in 3 cases, and pneumonia in 2. In 3 of these patients a streptococcal stomatitis had also been present during pregnancy.

Treatment and Progress

All the patients were given liver extract parenterally in ample doses. In 5 cases this resulted in a typical reticulocyte response within a week and a subsequent adequate rise in the red cell count. Ten patients were temporarily refractory to treatment for periods varying from eleven days to several months. All received intensive parenteral liver therapy, well-known preparations such as anahaemin, pernaemon forte, campolon, neohepatex, haemex, and reticulogen being used. In order to eliminate the possibility of the failure to respond being due to an inert batch, more than one brand was invariably administered to such refractory cases. In addition to liver extract, all the refractory cases were treated with iron, and many of them also received yeast and ascorbic acid. In spite of this treatment 6 cases continued to be refractory for a month or longer. In 12 of the severest cases life had to be sustained by blood transfusion because of the low blood level and the unsatisfactory clinical state. In some of the refractory cases blood had to be given repeatedly, sometimes over several weeks.

In some cases liver therapy resulted in the same dramatic haematological and clinical improvement as is seen in

Addisonian pernicious anaemia, but in others the response was delayed, and when it occurred the rise in red cells and haemoglobin was gradual and protracted. Fourteen of the cases eventually made a complete clinical and haematological recovery. One patient (Case 16) died after a transfusion reaction; another (Case 8) died six months after delivery, despite large doses of liver extract, iron, yeast, and ascorbic acid, and repeated blood transfusions; death was attributed to severe bronchiectasis and pyelonephritis.

Since all these patients have been under observation for only two years, or less, it is impossible to make any statement regarding the permanency of recovery. Four have been followed during periods of six to twenty-four months and have maintained satisfactory blood levels without further treatment.

Discussion

Consideration of our own findings as well as those of previous investigators (e.g., Osler, 1919; Stevenson, 1938) reveal that a considerable proportion of cases of "pernicious anaemia of pregnancy" fail to satisfy all the criteria that are usually required for a diagnosis of Addisonian pernicious anaemia. In our opinion, for the diagnosis of the latter condition the following features should be present: a blood picture displaying anisocytosis, macrocytosis, ovalocytosis, hyperchromia, leucopenia, and thrombocytopenia, and a histamine-fast achlorhydria. In none of our group of 16 cases were all these features present. Basing a diagnosis solely on the peripheral red cell picture, we should have designated 5 of our cases as classical pernicious anaemia, while 7 more would have required careful consideration, since the colour indices were considerably higher than would be expected in iron-deficiency anaemias of comparable severity. The outstanding features serving to differentiate many of our cases from Addisonian pernicious anaemia were the presence of free hydrochloric acid in the gastric juice and a lower frequency and degree of macrocytosis and ovalocytosis.

Examination of the sternal marrow obtained before and after beginning liver therapy revealed with one exception (Case 9) pictures identical with those found in Addisonian pernicious anaemia at equivalent stages, and clearly indicated that these anaemias have for their immediate cause arrested maturation of the megaloblasts. Accordingly we propose that the term "megaloblastic anaemia of pregnancy" should be substituted for the misleading name "pernicious anaemia of pregnancy" on the grounds that the megaloblastic appearance of the bone marrow is characteristic and constant, while the peripheral blood findings are variable. The varying blood pictures are probably due to coexisting deficiencies of other haematinic factors.

Owing to the varying peripheral blood picture it does not appear practicable to establish adequate criteria for diagnosis without examination of the sternal marrow. Since severely anaemic patients with colour indices within or below the normal range may respond promptly to liver extract it would follow that the institution of rational treatment is dependent upon sternal puncture. The alternative is the empirical administration to all such patients of liver extract in addition to iron. Although manifestly undesirable, empirical liver therapy is perhaps less deserving of censure in this instance than in the treatment of other types of anaemia, since megaloblastic anaemia of pregnancy is of temporary duration, and the patient is accordingly not permanently condemned to an expensive and tiresome treatment.

The aetiology of megaloblastic anaemia of pregnancy is still unsettled. The most acceptable explanation is that the primary cause lies in a temporary failure of secretion of the intrinsic factor of Castle by the stomach during the later months of pregnancy (Strauss and Castle, 1933). That the secretion of hydrochloric acid may be temporarily impaired in a considerable proportion of pregnant women has been established by Strauss and Castle (1932). Other factors held to be of importance are: (1) reduced intake of extrinsic factor consequent upon poor diet, capricious appetite, anorexia, and vomiting; (2) impaired absorption from the small intestine due to altered hydrogen-ion concentration of its contents secondary to reduced gastric acidity; and (3) increased demands by the foetus for haematinic principles. We are unable to express any opinion on impaired production of intrinsic factor by the stomach or failure of absorption by the small intestine, as we have made no special investigation of these points. With regard to diet, in some of our cases it was apparently satisfactory, but in others it was undoubtedly poor. Furthermore, in some patients undue anorexia and vomiting were known to have occurred, whereas in others no note of such symptoms appeared in the case records. Nevertheless, since the bone marrows were megaloblastic, it can be safely assumed that there was an insufficiency of liver factor for normoblastic erythropoiesis.

Ten of our cases were refractory to treatment for longer or shorter periods before they eventually responded. This failure suggests the existence of a state of temporary arrest of erythropoietic function consequent on the absence of some essential factor additional to the liver principle. A similar state of affairs not infrequently occurs in sprue, in which a megaloblastic marrow may fail to react to parenteral liver extract. One of us has previously noted (Davidson, 1939) that in this condition a response may occur when liver therapy is supplemented by a high-protein diet. This would suggest that some factor in protein is necessary for erythrocyte production, possibly in connexion with stroma formation.

An alternative hypothesis is that refractoriness to treatment is related to a functional inability of the bone marrow to utilize the various haematinic principles because of the profound strain of pregnancy and the shock of labour occurring in a severely anaemic patient. In this connexion we wish to draw attention to the disastrous fall in the blood count which may result from a normal blood loss in such women during childbirth. Data available to us show that a haemoglobin level of 30 to 40% before labour may drop to a figure of 15 to 20% immediately subsequent to delivery.

The inhibitory effects of sepsis on liver therapy have been widely accepted. In 6 of our cases it is possible that sepsis played a part in this delayed response to liver therapy, but one of us has had cases of Addisonian pernicious anaemia with severe pneumonia with blood counts of a million or less which responded promptly to liver therapy (Davidson, 1933). Furthermore, in some of our present group of pregnancy cases refractory to treatment no sepsis could be found.

Conclusions

The practical conclusions drawn from our experience on which we wish to lay particular emphasis may be stated as follows.

1. It should be recognized that a severe megaloblastic anaemia may occur during pregnancy or the puerperium although the colour index may be unity or less.

2. Despite the administration of large quantities of liver extract, iron, and yeast, no response may be obtained for a considerable time in a proportion of such patients.

3. Our experience indicates that the great majority of refractory cases eventually make a complete recovery if life is maintained by blood transfusions while persevering with vigorous haematinic treatment. A study of the Table will show that, no matter how severely anaemic the patient, a good prognosis can be given if these measures are carried out.

4. The paramount importance of recognition of anaemia during pregnancy cannot be stressed too strongly, as only by this means can the acute exacerbations which tend to occur during the last two months of pregnancy be prevented.

Summary

A severe type of anaemia associated with a megaloblastic bone marrow occurring during pregnancy and the puerperium has been defined and its points of resemblance to and distinction from Addisonian pernicious anaemia considered.

Sixteen cases have been recorded and their haematological, clinical, and therapeutic aspects discussed.

Ten of the cases were temporarily refractory to treatment with massive doses of liver extract, iron, and other haematinics.

Attention has been drawn to the vital importance of perseverance with intensive therapy in refractory cases and to the necessity for sustaining life by blood transfusions until a response is obtained.

On a basis of bone-marrow cytology, the term "megaloblastic anaemia of pregnancy and the puerperium" has been proposed for this type of anaemia.

We wish to thank our colleagues on the medical and obstetrical staffs of the Royal Infirmary of Edinburgh and the Western General Hospital, Edinburgh, for allowing us to investigate and report on the above cases. Two of us (L. J. D. and J. I.) were in receipt of a Crichton Research Scholarship and a Leckie Mactier Fellowship in Medicine respectively during the period of this investigation.

ASPHYXIA FOLLOWING DENTAL EXTRACTION IN A HAEMOPHILIAC

WITH A NOTE ON THE SPREAD OF INFECTION IN LUDWIG'S ANGINA

BY

C. L. ENDICOTT, L.D.S.
Director, Eastman Dental Clinic

J. H. MITCHELL, L.D.S.
Chief of Staff, Eastman Dental Clinic

AND

G. QVIST, F.R.C.S.
Late Surgical Registrar, Royal Free Hospital

The dangers of dental extraction in haemophilia are well recognized, and numerous cases of persistent haemorrhage are on record. The case here described is of interest on account of the anatomical extent of the haemorrhage, the extravasation of blood involving the deep cervical tissues as far down as the larynx, so that tracheotomy was necessary.

Case Report

The patient, a man aged 35, attended the Eastman Dental Clinic on Oct. 14, 1941, complaining of pain for two days localized to the right second lower molar tooth. He did not admit any previous history of bleeding, so that when dental extraction was performed it was not known that he was a haemophiliac.

His history, which was obtained later, showed that he had in fact suffered from recurrent haemorrhages from the age of 19. There was no abnormality of bleeding among his parents and six brothers. When 19 years old he was admitted to St. Bartholomew's Hospital with a large haematoma of the thigh following a trivial injury, and was readmitted a year later for haemorrhage after dental extraction, when bleeding continued for one week and 550 c.cm. of blood was given. On this occasion the blood-coagulation time was 17½ minutes; after the blood transfusion it was 8¾ minutes. At the age of 24 he was admitted to Guy's Hospital with a haematoma of the rectus abdominis and haemarthrosis of the left knee. Bleeding-time was normal and coagulation time was 13 minutes on one occasion (12/5/30) and 16 minutes on a second occasion (24/12/30) (control, 6 minutes). He was readmitted to St. Bartholomew's at the age of 31 with a haematoma of the forearm. The bleeding-time was then 2 minutes 10 seconds and coagulation time 3 minutes 30 seconds (27/8/37) (control, 2 minutes 10 seconds); platelets, 244,000.

When seen on Oct. 14, 1941, the patient had a tender loose second right lower molar, which was removed under gas anaesthesia. There was no undue difficulty or bleeding, and the patient went home. He returned in the afternoon, 5 hours later, bleeding from the tooth socket, which he stated had begun on the way home. The usual methods of control were attempted—plugging with dry gauze, adrenaline gauze, etc.—without relief. The patient was kept in the casualty ward, but in spite of repeated packing slow bleeding continued. Early the next morning, 18 hours after extraction, examination of the mouth showed that bleeding was proceeding from the gum at the site of extraction just behind the lower right first molar. Blood was welling up slowly from the depths of the socket, and there was no evidence of any tear of the mucosa other than at the actual situation of the extracted second molar. There was some swelling of the floor of the mouth just medial to the molar region, with the appearance of a submucosal haematoma. Two catgut stitches were introduced, closing over the gum, and external bleeding ceased immediately. Bleeding returned after two hours, and a third stitch was put in; no further haemorrhage occurred from this site. At this time, 24 hours after extraction, it was noted that the submucous swelling of the right side of the floor of the mouth had increased considerably, and there was now in addition a haematoma of the right side of the tongue and swelling of the right submaxillary region of the neck. It was believed that, bleeding from the gum having been controlled, tension in the tissues would not have to be very great to check what was regarded as a capillary ooze. Blood transfusion was begun.

During the next few hours the haematoma of the tongue spread to involve the whole organ, and swelling of the neck extended downwards, mostly on the right. During the course of the next day it became obvious that the larynx was being involved. Stridor was present and respiration was embarrassed, so that tracheotomy was necessary (54 hours after extraction). Actually breathing became extremely difficult on lowering the patient into the semi-supine position, and consciousness was lost just after incising the skin under local anaesthesia. On re-establishment of an airway with the tracheotomy tube, consciousness was recovered rapidly. The tracheotomy wound oozed continually and severe epistaxis started, and in spite of continued blood transfusion the patient died a few hours later, 66 hours after the extraction.

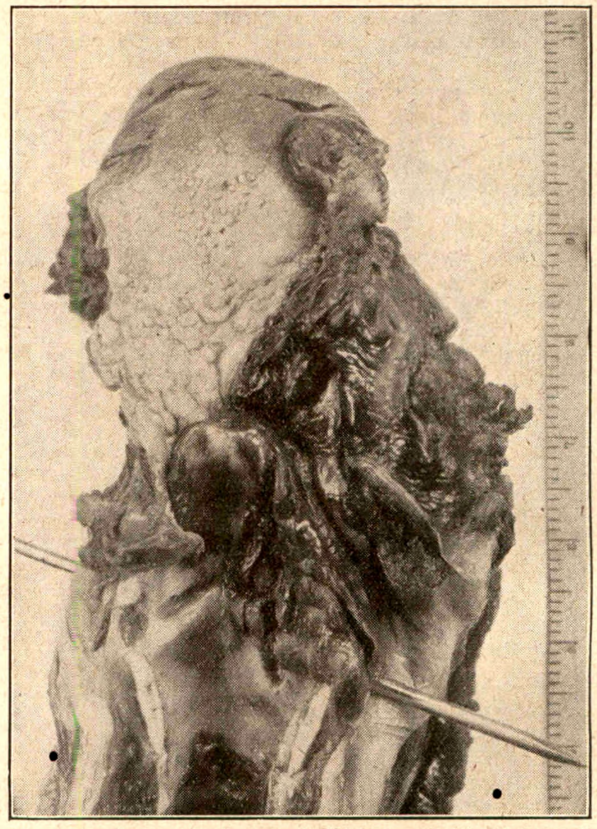

FIG. 1.—Specimen showing infiltration of blood into the mucous membrane of the larynx and upper part of the trachea.

Necropsy confirmed the presence of massive infiltration of the cervical tissues with blood, extending from the floor of the mouth and tongue down to the larynx and upper part of the trachea. The epiglottis and aryepiglottic folds were much swollen with blood and oedema in the submucosa, and the mucous membrane of the larynx and upper part of the trachea was infiltrated with blood, more marked on the right (Fig. 1). Careful search was made for a source of bleeding outside the gum, but none could be found.

Commentary

Several points of interest arise from consideration of this case:

1. *Source of Haemorrhage.*—The source of bleeding seems to have been a capillary ooze from the mucoperiosteum of the alveolus. Although external haemorrhage was controlled by stitches, blood must still have been escaping into the submucosa of the floor of the mouth. Extraction had been simple and trauma slight.

2. *Control of Haemorrhage in Haemophilia.*—It is doubtful if in the present state of knowledge it is possible to take adequate pre-operative measures to control haemorrhage in haemophilia. The time-honoured premedications with calcium and other agents are recognized to be of little value, the only promising one of these, according to Mead (1940), being intensive feeding with citrus fruit. Tainter, Throndson, and Richardson (1939) after an investigation of various agents concluded that "the results of this study leave no doubt that the agents commonly advocated for oral administration as haemostatics in dentistry are not effective when so used. The dental practitioner is advised to direct his efforts at controlling haemorrhage to local application of demonstrably effective agents rather than to try to speed up the coagulation processes by systemic medication." Perhaps the safest method of dealing with the problem is by slow exfoliation of the tooth, using a rubber band as recommended by Birch and Snider (1939).

3. *Path of Extravasation of Blood.*—A further point that arises is in connexion with the path of the blood down into the neck. It is quite clear that in this case blood extravasated from the floor of the mouth downwards through the base of the tongue in the plane above and behind the mylohyoid muscles and the hyoid, thus reaching the submucous tissues of the aryepiglottic region and thence the submucosa of the larynx. It provides an admirable illustration of the path of spread of infection in Ludwig's angina.

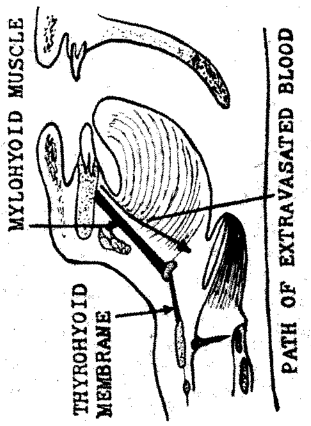

FIG. 2.—Diagram showing the relation between the musculo-membranous layer and the path taken by extravasated blood.

A most important anatomical feature in the neck influencing the spread of inflammatory fluids is the musculo-membranous layer represented by the mylohyoid muscles, the hyoid bone, and the thyrohyoid membrane (Fig. 2). Infections of the floor of the mouth and submaxillary region can be considered clinically in two groups according to their anatomical relation to this layer, this being the most important factor in prognosis and treatment, especially with reference to involvement of the larynx. Cellulitis primarily situated *below* the mylohyoid, as from a lymphadenitis of the submaxillary glands, if it extends downwards in the neck, will be *superficial* to the thyrohyoid membrane, and therefore does not endanger the larynx. Infections which are primarily in the submucosa of the floor of the mouth *above* the mylohyoid may easily track downwards, and will then be *deep* to the thyrohyoid membrane, thus involving the submucous layer of the larynx, this path of spread being well illustrated by the extravasation of blood in the case described above (Fig. 2).

Oedema of the larynx is therefore a complication essentially to be expected in infections above the mylohyoid—i.e., of the floor of the mouth or tongue. It is true that oedema of the larynx may complicate a superficial infection of the neck by spread along the stylopharyngeus to the laryngeal submucosa, as pointed out by Hamilton Bailey (1931), but this must be extremely rare. Oedema of the larynx is nearly always a complication of infection *above* the mylohyoid—that is to say, it is to be feared in true Ludwig's angina, and not in the superficial infections of the neck below and anterior to the mylohyoid-thyrohyoid layer which are often incorrectly called Ludwig's angina.

It is fortunate, therefore, that most dental infections spreading out from the lower alveolus reach the periosteum on the labial border of the gum owing to the thinner layer of bone on this aspect of the alveolus (Hamilton Bailey). If infection spreads downwards it will then be superficial in the neck. In the region of the third molar the alveolar bone is thinner on the lingual side, and dental infections may thus reach the submucosa of the floor of the mouth; spread downwards will then be above the mylohyoid, in the base of the tongue—a true Ludwig's angina.

Summary

A case of asphyxia following dental extraction in a haemophiliac is described. Obstruction of the airway was due to massive haemorrhagic infiltration of the floor of the mouth.

Control of haemorrhage in haemophilia is briefly discussed.

The path of extravasation of blood and inflammatory fluids into the neck is discussed, the importance of the mylohyoid muscle layer being stressed. Oedema of the larynx is essentially a complication of infections *above* the mylohyoid, and very rarely occurs in infections superficial to this layer.

We are indebted to the Registrars at St. Bartholomew's Hospital and Guy's Hospital for access to old notes.

INSULIN HYPOGLYCAEMIC COMA
WITH A REPORT OF TWO FATAL CASES

BY

E. H. ROCHE, M.C., M.D.Lond., F.R.A.C.P.

Physician to the Auckland Public Hospital, New Zealand

Before the introduction of protamine-insulin, deaths from insulin hypoglycaemic coma were very rare, and were confined to cases of gross overdosage with insulin or cases in which the sudden onset of coma caused the patient to fall into water or sustain serious injury. The ordinary hypoglycaemic attack was as a rule of short duration, and coma, if promptly treated, was practically never fatal. The records of the Auckland Public Hospital (800 beds) from the introduction of insulin to May 31, 1941, do not include a single fatal case. The possible effect of protamine-insulin, however, upon the character and outcome of hypoglycaemic coma has not yet been fully studied; consequently, the occurrence within a period of six weeks of two fatal cases in which the usual treatment was of no avail may be considered worthy of record.

Case I

This patient, a man aged 50, was drawing a military pension for achlorhydria. He had undergone an operation for ischiorectal abscess in August, 1937, but urine tests do not seem to have been made. He was admitted to the Auckland Public Hospital on May 5, 1941, with 6 months' history of polyuria, thirst, and loss of weight and strength. His blood sugar was 374 mg. per 100 c.cm. This and all subsequent blood-sugar estimations were made by the ordinary method of Folin and Wu. He was quickly stabilized on a diet of carbohydrate 200 g., protein 80 g., and fat 90 g., with a morning injection of zinc-protamine-insulin 20 units and ordinary insulin 16 units. On this dosage he had for 11 days consistently shown a small amount of sugar in specimens taken at 9 and 11 a.m., and frequently also at 4 p.m., but those taken before breakfast and at night were for the most part sugar-free. To prevent this small daily loss of sugar the ordinary insulin was increased from 16 to 20 units on May 30, and the next day he was transferred to a Returned Soldiers' Hospital for further observation.

On June 3 he left the Soldiers' Hospital at 10 a.m. apparently quite well, and at 12.20 p.m. was readmitted to the Public

Hospital in deep coma. The pupils were small and fixed, but all other reflexes were brisk. The cranial nerves, so far as they could be examined, were intact. The pulse was full and bounding at 60 a minute, and the temperature was 95°. Radiant heat was applied and the blood sugar was estimated immediately and found to be 41 mg. per 100 c.cm. At 1 p.m., therefore, he was given 100 c.cm. of 25% glucose intravenously by syringe and 250 c.cm. of 5% glucose by rectal drip, and a catheter was tied in so that the excretion of sugar could be closely watched. At 2 p.m. a further 100 c.cm. of 25% glucose was given by syringe, making a total of 50 g. of glucose intravenously, in addition to that which might have been absorbed per rectum. In spite of this, at 3 p.m. the blood sugar had fallen to the extremely low level of 16 mg. per 100 c.cm. The total non-protein nitrogen was 22 mg. per 100 c.cm. Two pints of 5% glucose-saline was then added to the rectal drip, and at 4 p.m. 500 c.cm. of 10% glucose was given by rapid intravenous drip. At 5 p.m. the blood sugar had risen to 80 mg., but the patient remained in deep coma. The temperature had risen to 100.6°, and thereafter remained moderately elevated and somewhat erratic. At 9 p.m. he received a further 250 c.cm. of 10% glucose-saline, and at 10 p.m. the blood sugar had risen to 190 mg., Benedict's urine test then giving a brick-red deposit (8 drops of urine to 5 c.cm. reagent—boiling-water bath for 5 minutes).

Thereafter for the next 7 days hourly specimens were tested and the greatest care was taken to maintain an adequate blood-sugar level, in the forlorn hope that the cerebral depression might lift. Throughout this period small amounts of sugar—green to yellow—were present in nearly every specimen of urine, but the Rothera test remained for the most part negative. By continuous intravenous drip an average of nearly 6 pints of 5% glucose-saline was administered daily, and small doses of insulin were given when indicated. Details of this treatment together with the temperature are recorded on the Chart. By 11 p.m. on June 7 he had recovered consciousness sufficiently to make some attempt at speech and to take 6 oz. of fluid containing 25 g. of glucose by mouth. Next day he took 18 oz. of fluid by mouth, and, though still stuporous, had a few moderately lucid intervals. On the seventh day he took 24 oz. of fluid by mouth, but remained stuporous. At 8 a.m. on June 10 he became suddenly weaker, lapsed into deep coma, and died 2 hours later. During the last 2 days approximately 0.5% sugar had been present in every specimen and the Rothera test had remained consistently negative.

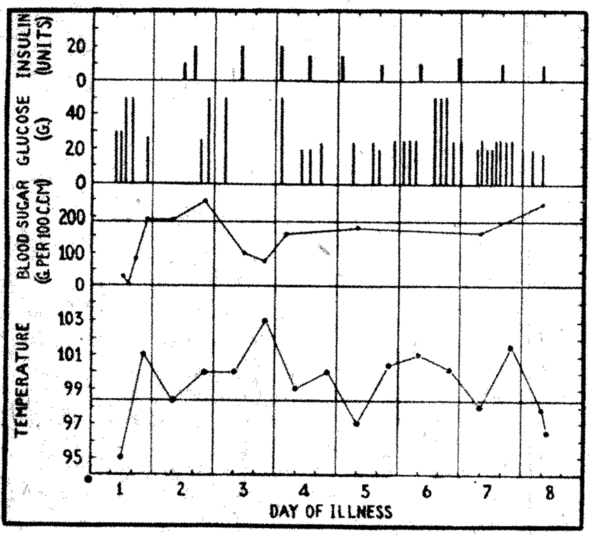

Chart of Case I

The necropsy revealed a pancreas of normal appearance, as were all other organs except the lungs, which showed early patchy bronchopneumonia at both bases, and the brain, which showed congestion of the surface vessels and, microscopically, perivascular softening in the thalamus and caudate and lenticular nuclei.

Case II

This patient, a man aged 55, was admitted to the Auckland Public Hospital on July 3, 1941, with 3 years' history of loss of weight, lassitude, frequency, and thirst. His urine gave a brick-red Benedict and a negative Rothera reaction, and the blood sugar 3 hours after breakfast was 328 mg. per 100 c.cm. He responded rapidly to treatment and was quickly stabilized on a morning dose of 24 units of zinc-protamine-insulin.

On July 11 he was discharged from the ward and referred for further supervision to the diabetic clinic, where, however, he did not report. On July 21 he drove into town with his wife. The morning was so fully occupied with calls that he missed his 12 o'clock lunch. On the way home he drove recklessly, and occasionally swerved without reason across the centre of the road. At 12.30 p.m. he collided with another vehicle, wrecking his own car. He was shaken, but escaped bodily injury and had no difficulty in walking 100 yards and giving detailed instructions as to his car. Arriving home at 1.30 p.m., he sat down heavily and announced that he felt very hungry. His wife hastened to prepare lunch, but he had scarcely begun to eat when he rolled off his chair and could not be roused. A doctor who was called diagnosed diabetic coma and, finding in his room a syringe and bottle of insulin (protamine-zinc), gave him an injection of 12 units. At 3.45 p.m. he was admitted to hospital in deep coma. The pupils were small and fixed. His throat was so thickly coated with mucus as to impede respiration and cause cyanosis: 4 oz. of mucus was aspirated. The blood sugar on admission was at the very low level of 15 mg. per 100 c.cm. The temperature was 98.4°, pulse 96, and respirations 16. Radiant heat was applied, and 50 g. of glucose in normal saline was given at once intravenously. There was a definite response, deep coma giving place to restlessness and the pupils dilating to a diameter of 1/8 inch and reacting sluggishly to light. At 4 p.m. 50 g. was given intravenously and at 6 p.m. 25 g., but without further recovery of consciousness. At 8 p.m. a specimen was taken for blood-sugar estimation, but before the completion of this test the patient's condition suddenly deteriorated, the respiration rate fell to 8 a minute, further mucus collected, and cyanosis developed. Aspiration and stimulants met with no response, and death ensued at 9.15 p.m. The blood sugar at 8 p.m. proved to be only 20 mg. per 100 c.cm.

The post-mortem examination revealed a poorly nourished body with no marks of injury. The pancreas was rather small but otherwise normal, and all the other organs except the lungs and brain appeared to be normal. The lungs showed in the right upper lobe a primary caseous tuberculous lesion about half an inch in diameter, with involvement of the corresponding root gland. The brain was very oedematous, with marked excess of cerebrospinal fluid upon its surface. There was general softening, especially in the cerebellum.

Discussion

A. Causes of Coma

Both cases had been under observation in hospital until 3 days (Case I) and 10 days (Case II) before the onset of coma. During that period they behaved as ordinary diabetic patients of average intelligence and their response to insulin and diet was normal. They had been carefully instructed as to their diets and were fully competent to give their own injections of insulin. Further, the subsequent necropsy failed to reveal any organic cause of hypoglycaemia such as tumour of the pancreas or pituitary or any disease of the suprarenal or thyroid glands or liver or pons. Our study of these cases suggests that coma was at least partly due to the following:

1. In Case II the full cumulative effect of zinc-protamine-insulin may not have developed at the time of discharge from hospital. When this effect was obtained, perhaps on the day after discharge, it may have been too great.

2. The shock of the motor accident in Case II may have disturbed the endocrine balance in such a way as to increase sugar utilization.

3. Escape from Public Hospital discipline may have resulted in considerable increase in bodily exercise with consequent improvement in sugar utilization. This effect would be enhanced in Case I by the small increase of insulin (from 36 to 40 units) which was ordered, inadvisedly, on the day before discharge.

4. The ever-present risk of an error in the measurement of insulin and the natural tendency of a man feeling vaguely unwell to prescribe for himself an extra dose of anything that has previously done him good.

B. The Fatal Outcome

Necropsy revealed organic changes in the brain consisting of perivascular softening in the thalamus and lenticular and caudate nuclei in Case I, and of an abnormal amount of cerebrospinal fluid and general oedema of the brain with softening, particularly in the cerebellum, in Case II. These changes, or their physico-chemical precursors, were undoubtedly the cause of death and must have been responsible for the continuance of coma in Case I when, 4½ hours from the onset, the blood sugar returned to normal. Other possible causes such as encephalitis and head injury must be excluded. In Case I the history is unlike that of encephalitis, and the pyrexia can be accounted for by the bronchopneumonia. There was no evidence of head injury in Case II.

There remains only hypoglycaemia to account for the cerebral damage. Pathological changes, including chromatolysis, vacuolation of protoplasm, fragmentation of cell processes, pyknosis of nuclei, petechial haemorrhages, and oedema widely and irregularly disseminated through the nervous system, have been described by Terplan (1932), Baker and Lufkin (1937), and many others, in fatal cases of pancreatic tumour and insulin hypoglycaemic coma in man and animals. Baker and Lufkin, however, being unable to find similar changes in hypoglycaemic rabbits upon which necropsy was performed immediately after death, considered that most if not all the changes observed in their 3 human cases occurred post mortem. They believed, further, that similar changes could be found in normal brains at the same period after death and doubted whether hypoglycaemia had played any part in their causation. Baker (1939), however, later found incontrovertible evidence of hypoglycaemic cerebral damage. Among his 26 rabbits 7 were examined after a single induction of hypoglycaemia with convulsions. A great many petechial haemorrhages and widespread severe demyelination and encephalomalacia were demonstrated. In these experiments the hypoglycaemia, though doubtless severe, was limited to an hour's duration, and only one rabbit actually died in coma. Accornero (1939) and Ferraro and Jervis (1939) present corroborative evidence.

Tyler (1941) confirmed the presence of hypoglycaemic brain damage in cats even when convulsions were prevented by sodium pentobarbital (nembutal). He made the important observation that a fall of body temperature and the administration of drugs such as nembutal, which depressed cerebral metabolism, gave an appreciable measure of protection against brain damage. He attributed the damage to inadequate cerebral respiration, in which glucose plays a vital part. We cannot escape the conclusion that severe hypoglycaemia as a cause of cerebral damage and death is now well established. But hypoglycaemia pushed to the stage of convulsions is a common and comparatively safe method of treatment for schizophrenia. An interesting study of therapeutic hypoglycaemia in 25 cases of schizophrenia has been made by Day, Niver, and Greenberg (1938). After shock-doses of ordinary insulin, estimations of glucose in the blood and cerebrospinal fluid were made by Benedict's method. The Folin-Wu method, which I used, is sensitive to many non-glucose-reducing substances equivalent to 20 to 27 mg. of glucose per 100 c.cm. of blood; the Benedict method is insensitive to all but a few, equivalent to 4 to 8 mg. per 100 c.cm. of blood. It follows, therefore, that when comparing the results obtained by these different methods a correction of 15 to 20 mg. per 100 c.cm. of blood must first be applied. Out of 28 inductions of hypoglycaemia by Day and his colleagues, in one case the blood sugar remained for 2½ hours between 5 and 20 mg. per 100 c.cm. (Benedict). In every case consciousness was promptly restored on the administration of 15 g. of glucose intravenously, and no after-effects were observed.

The lowest blood sugar recorded in my two cases was lower than that present in any of the schizophrenic cases, allowing for the effect of the non-glucose-reducing substances. In fact, with the correction for the Folin-Wu method there was apparently a complete absence of glucose from the blood. This aglycaemia may have lasted from 1 p.m. till 3 to 4 p.m. (2 to 3 hours). In Case II the duration of aglycaemia was about 4 hours, and this implies that at some time during that period there was free insulin in the blood with no glucose upon which to act. In Case I also the same condition was almost certainly present. The effect of such a glucose vacuum may well be more destructive to the nervous tissues than any degree of mere hypoglycaemia in which the blood retains a reserve of glucose, however small. In view of Tyler's work previously mentioned it is probable that the destructive effect of aglycaemia was increased in both our cases by the application of radiant heat. It is possible that the tissues of diabetics, inured to a raised blood sugar, would be more susceptible than those of normal persons to damage from sudden extreme hypoglycaemia.

Conclusions

Too much must not be deduced from evidence based upon limited clinical material, but we venture to draw the following tentative conclusions:

1. Zinc-protamine-insulin, while constituting an advance in the treatment of diabetes and while diminishing the frequency and in most cases the severity of hypoglycaemic symptoms, adds seriously to the gravity of hypoglycaemic coma when established.

2. Patients who are exposed to shock and strain while under treatment with zinc-protamine-insulin may develop profound hypoglycaemia of rapid onset and fatal outcome.

3. Patients who develop hypoglycaemic coma while under treatment with zinc-protamine-insulin should be treated much more vigorously than is necessary for similar cases under ordinary insulin. We suggest the following measures in such cases:

(*a*) An immediate intravenous injection of 100 g. of glucose (400 c.cm. of 25% solution) by syringe or cannula—the same dose to be repeated within half an hour if necessary. In the absence of immediate intravenous facilities a still larger dose should be administered by stomach-tube.

(*b*) An immediate subcutaneous injection of adrenaline 15 minims and pituitrin 1 c.cm.

(*c*) Except perhaps in cases of extreme fall in body temperature no warmth should be applied and no cerebral stimulants given.

Summary

An account is given of two cases of insulin hypoglycaemic coma which failed to respond to prompt and moderately vigorous treatment. In each case there was a period of aglycaemia with probably excess of free insulin in the blood. The damaging effect of aglycaemia upon the brain and the relative safety of insulin-shock treatment for schizophrenia are discussed. Attention is drawn to the gravity of hypoglycaemic coma in diabetic patients under treatment with zinc-protamine-insulin, and measures which should prove effective are suggested.

My thanks are due to Drs. W. H. Jackson, R. Rogers, and H. C. Tuck, house-physicians, for constant vigilance and unremitting care in the treatment of the cases, and to Dr. W. Gilmour and his staff for biochemical and post-mortem examinations.

A CASE OF HUMAN ISO-AGGLUTININ ANTI-M

BY

J. L. HAMILTON PATERSON, M.D.
R. R. RACE,* M.R.C.S., L.R.C.P.
AND
G. L. TAYLOR,* M.D., Ph.D., M.R.C.P.

(*From Redhill County Hospital, Edgware, and the Galton Laboratory, Department of Pathology, Cambridge*)

Antibodies for diagnosing the M-N blood-group factors have to be made by injecting appropriate red blood cells into an animal—nearly always a rabbit—and later absorbing suitably the rabbit serum to remove unwanted species antibodies. Because anti-M and anti-N do not occur naturally in man serum, and because M and N do not seem to be antigenic for man, the M-N groups can be neglected almost entirely in considering compatibility in blood transfusion. Wiener (1941) wrote: "Only 3 individuals have been observed to date with natural isoagglutinins anti-M, none with anti-N, among several hundreds of thousands of individuals tested." He had previously (Wiener, 1939) mentioned three cases of anti-M and had given references to two of them. The first had been reported, without details being given, by Wolff and Jonnson (1933, p. 84), the second by Friedenreich (1937), and another case, which may be the third one referred to by Wiener, has been described by Moureau and Lambert (1939a, 1939b).

---

* Working on behalf of the Medical Research Council.

Details of the Case

Recently, as a result of testing, against the red cells of potential donors, the serum of a woman (M. W.) who might have needed a transfusion in connexion with parturition, an antibody, apparently anti-M, has been discovered. No transfusion was given. M. W. was 28 years of age and pregnant for the fourth time. Her blood group was ON and she was Rh-positive. Friedenreich's case was that of an infant aged 2½ months, of group ON, whilst Moureau and Lambert's case was that of a man of group A₁BN aged 35. Friedenreich intended to find out what became of the anti-M as the child grew up, but it died of an epidemic disease when 9 months old.

Serum obtained from M. W. four months after her confinement was tested against the red cells of 20 persons belonging to group O. Equal volumes of serum and cell suspension—about 5% whole blood, as judged by eye—were mixed in 2 in. by 1/4 in. precipitin tubes; readings were made after the tubes had stood at room temperature for two hours. Undoubted and clear-cut agglutination was found in 14 of the mixtures; in some the reactions were seen by the naked eye, in others by using a microscope (see Taylor, Race, Prior, and Ikin, 1942). The 14 lots of cells which were agglutinated all contained the agglutinogen M; 5 were OM and 9 OMN. On the whole the reactions given by the homozygous M cells were stronger than those given by the heterozygous MN cells. The 6 donors whose cells did not react belonged to group ON, and so lacked the antigen M. When the reactions given by a known and an unknown antibody and the same panel of red cells are identical the odds in favour of the two antibodies being the same can easily be calculated. The probability that the apparent identity of the two antibodies is due entirely to chance is given by the formula $\frac{a!\,b!}{n!}$,* where n is the number in the panel and a and b the numbers of positive and negative reactors. Applying the present figures, we get $\frac{14!\,6!}{20!}$, or $\frac{1}{38,760}$, as the probability that the identity of the results is due merely to chance; in other words, the odds in favour of the antibody in M. W.'s serum being anti-M are 38,759 to 1. After absorption of the serum in the cold with OM cells the reaction, both in the cold and at room temperature, disappeared, while absorption with ON cells did not remove the antibody.

Table showing Titration of Serum of M. W.

Temperature	Serum Dilution	Cells			
		OM	OMN	ON	M. W.
2° C. ..	1/1	V	+ +	—	—
	1/2	V	w		
	1/4	+ +	—		
	1/8	—			
Room temp.	1/1	V	(+)	—	—
	1/2	+ +	—		
	1/4	—			
37° C.	1/1	—	—	—	—

No reaction is scored as negative without a microscopical examination; reactions weaker than V were determined with a microscope.

C = Clumps of cells in clear surrounding fluid visible to naked eye.

V = Somewhat weaker reaction, with clumps distinctly visible to naked eye, although surrounding fluid is not clear.

+ + = Very big clumps under microscope; + = not quite such big clumps; (+) = less than +.

w = Definite weak reaction in which there is a uniform distribution of very small clumps of about 6 to 8 cells.

Titration of the antibody in M. W.'s serum, detailed in the Table, showed that it was most active in the cold, less active at room temperature, and undetectable at 37° C.; the homozygous M reacted better than the heterozygous MN cells. This iso-agglutinin anti-M, like those described by Friedenreich and by Moureau and Lambert, had some of the characteristics of a cold agglutinin.

Both Friedenreich, and Moureau and Lambert, examined the relatives of their patients, but found no evidence that the occurrence of the iso-agglutinin anti-M was familial. M. W.'s father is dead and her mother and one sister are OMN; a second sister belongs to group ON, but anti-M has not been discovered in her serum. The husband of M. W. is OM and all their children will therefore be OMN. It might be suggested that the anti-M in M. W.'s serum resulted from the stimulus provided by the antigen M, present in the cells of all her foetuses, but there is no evidence to support this possibility. Her four pregnancies were: 1935, female, 6 lb., alive and well; 1937, male, 6 lb., alive and well; 1939, miscarriage, 3/12; 1941, female, premature, alive and well. No child has shown any signs of erythroblastosis foetalis. The anti-M was not the result of a previous transfusion, for none had been given.

Summary and Conclusions

Iso-agglutinin anti-M has been found in the serum of a woman as the result of tests made to obtain a suitable blood transfusion donor for her.

Although the occurrence of iso-agglutinin anti-M must be exceedingly rare, the case here reported shows that its presence may interfere with the selection of a suitable blood transfusion donor for a person in whose serum this antibody appears.

FURTHER DATA CONCERNING HUMAN FERTILITY

BY

G. PUGH SMITH, B.Sc., Ph.D.

University College of South Wales and Monmouthshire, Cardiff

Recent contributions to knowledge concerning the period of ovulation and successful fertilization in the human female (Weinstock, 1934) have thrown some doubt upon the validity of Knaus's theory of the relation between the dates of ovulation and onset of menstruation, and upon the deductions which may be made concerning the existence and duration of a pre-menstrual "safe period." Data quoted by Pryde (1941) and by Fleck, Snedeker, and Rock (1940), however, tend, within limits, to substantiate Knaus's views. Further data given below support the following hypotheses: (i) if fertilization does not occur menstruation follows approximately 15 days after ovulation; (ii) within limits there is a "safe" or infertile period a few days before the onset of the next menstrual cycle; (iii) an average "safe period" can be predicted with fair accuracy by a sufficiently extended study of the individual's menstrual periodicity.

The Present Investigation

The data concern all the acts of uncontraceptive intercourse during 31 menstrual cycles after which pregnancy did not occur and one cycle which was followed, as intended, by pregnancy. Pregnancy intended in cycles 30 and 31 was not fulfilled owing to the intermittent absence of one partner. There were no other acts in which contraceptive methods were used. An accurate record was kept of the dates and duration of each cycle, and the dates on which intercourse took place. A table was drawn up with vertical columns for the individual days of a cycle, starting with the first day of menstruation, data for successive cycles being recorded horizontally (see Chart). As each cycle was completed the last day was marked, and also the hypothetical day of ovulation, assuming it to be 15 days *before the first day of the next cycle.* A box was drawn round the supposed fertile period of each cycle, assuming it to be 3 days before and 1 day after the hypothetical day of ovulation: it was assumed that the maximum period for which spermatozoa were able to withstand the body temperature of 98.4° F. *and still remain active enough to penetrate the ovum* was 72 hours, and that the viability of the ovum after shedding was up to 48 hours. On these premisses the safe period for a 28-day cycle ran from the 16th day onwards. However, owing to variation in cycle length this assumption could not be applied as a generalization to all cycles. Therefore, before attempting uncontraceptive intercourse the variation in length of the menstrual cycle of the same partner was ascertained by recording the lengths of 21 successive cycles (Chart and Table I). It was decided that in her case, if Knaus's theory was correct, and in spite of one longer cycle on June 27, 1937, a "safe period" would be assumed to run from the 20th day to the end of any cycle, and that intercourse before this and later than the 9th day would invite fertilization. Guided by this assumption, during a further 29 cycles sexual activity was largely avoided between the 9th and 20th days. On certain occasions this practice was deliberately discarded. As previously stated, sexual activity in cycles 30 and 31 was intended to fall within the hypothetical fertile period, but this arrangement was not fulfilled. In cycle 32, however, pregnancy ensued. The details are shown graphically in the Chart.

TABLE I.—*Duration of Cycles*

Period	Duration (Days)													Total No. of Cycles
	25	26	27	28	29	30	31	32	33	34	35	36	37	
1937–8	1	1	2	9	1	4	2	0	0	1	0	0	0	21
1938–41 ..	0	0	4	10	8	4	1	2	1	0	0	0	1	31
Total	1	1	6	19	9	8	3	2	1	1	0	0	1	52

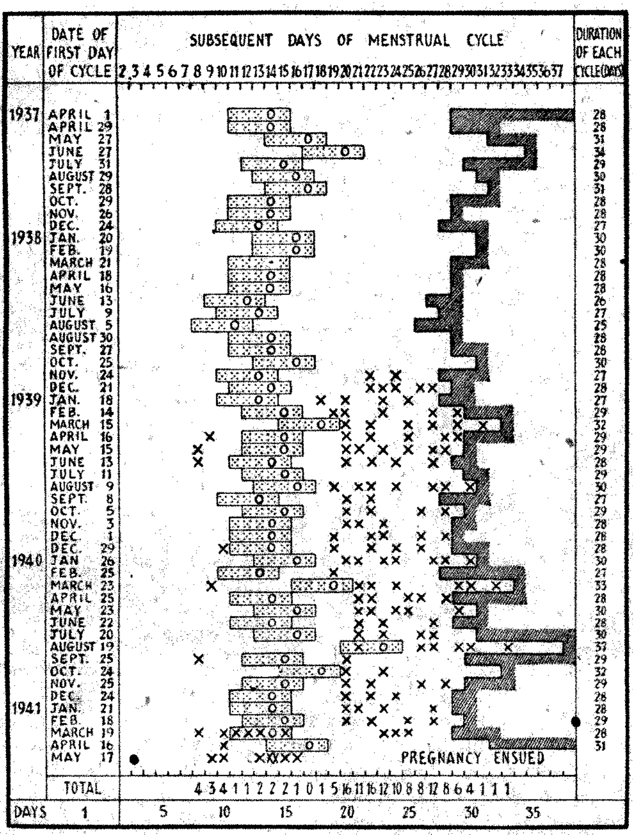

Chart showing distribution of uncontraceptive acts of intercourse throughout 32 menstrual cycles, the variation in length of which and of 21 other cycles is illustrated. The narrower assumed limits of the fertile period in each cycle are also shown.

When predicting the fertile period of a given individual the most convenient way is to count from the beginning of a cycle. If, however, the dates of ovulation and onset of the following menses are more closely related than the date of the preceding menses is to ovulation, then, taking variation of cycle length into account, it is difficult to generalize by indicating the "safe period" in terms of the *beginning* of the cycle. When the data are arranged as tabulated by Pryde—i.e., assuming the fertile period always to occur from the 10th to 15th day of a cycle (Table II)—it will be seen that in the non-fertile cycles 1 to 31 there was intercourse on some of the days of this very period, although it happens that in cycle 32, which was followed by pregnancy, there was intercourse on all days of the fertile period except the 12th.

Time Relation between Menstruation and Ovulation

However, in considering the period of fertility in the light of Knaus's views—i.e., the relation between the onset of menstruation and the number of days prior to it when ovulation occurs—it is more appropriate, in arranging the data, to relate the date of intercourse *to the date of onset of the following cycle* (Table III).

The data in the Chart and Table III show that in this particular case during 31 cycles there was a period of infertility up to a maximum of 13 days *before the onset* of the next menstrual cycle. The Chart and Table II show that the assumption that this infertile period ran from at least the 20th day of any cycle was fairly well justified. In view of the longer cycle beginning on March 23, 1940, the 21st day onwards was temporarily resorted to as being safer for uncontraceptive intercourse, although the unexpected abnormally long cycle beginning on August 19, 1940, would suggest that the 25th day was more appropriate. The occurrence of such a long cycle after a succession of shorter ones may explain the failure of some predictions of infertile periods (Fleck *et al.*). In spite of this "escape," however, in the case cited, the 20th day was again assumed to be the beginning of the infertile period. It is unfortunate that there is no record whether any ailment (cold, etc.) occurred during the early part of the cycle beginning on August 19, 1940, that might be considered a possible factor in the postponement of ovulation.

From Table II it is clear that in the 32nd (fertile) cycle fertilization occurred between the 9th and 16th days.

The foregoing conclusions depend upon the assumption that, throughout, the spermatozoa were capable of fertilizing. There was a long period of abstention from regular sexual activity between the onset of menstruation and the 20th day of each cycle. Both partners were young and healthy, and in a good state of nutritional well-being.

TABLE III.—*Distribution of Acts of Uncontraceptive Intercourse shown on Days before the Onset of the Next Cycle*

Menstruation begins		

Summary

Data are given showing the variation of 52 menstrual cycles in the same individual, and the relation between an assumed fertile period and the beginning and end of each cycle.

Ovulation is assumed to occur 15 days before the onset of the following menses.

Records of uncontraceptive intercourse during 31 infertile cycles show that there were occasions when intercourse took place as much as 13 days before the beginning of the next cycle without ensuing pregnancy. Intercourse was most frequent up to 10 days before the next cycle without pregnancy resulting.

Intercourse which took place on the 9th, 10th, and 13th to 16th days after the beginning of a cycle was followed by pregnancy.

It is concluded that prediction of the narrower limits of the fertile period of an individual can only be made by counting back from the beginning of the next cycle.

Only the wider limits of the fertile period may be predicted by counting from the beginning of the same cycle, requiring a knowledge of the variation of menstrual periodicity.

W. M. Fowler and Adelaide P. Barer (*J. Amer. med. Ass.*, 1942, **115**, 421), investigating the rate of regeneration of haemoglobin in blood donors, found that the average drop in blood haemoglobin was 2.3 g. after the removal of 555 c.cm. of blood, and that the average time needed to replace this amount of haemoglobin was 49.6 days. Longer recovery periods were associated with a steeper fall in haemoglobin and could not be correlated with initial blood haemoglobin values. Hb was regenerated in man at the rate of 0.049 g. per 100 c.cm. of blood a day, and in women at the rate of 0.040 g. The administration of 1 g. of iron and ammonium citrates a day increased the daily haemoglobin regeneration by 49% and shortened the recovery period from 49.6 to 35.2 days. This was noticed during the first period, but the effect after subsequent blood donations became progressively less. If the haemoglobin of the donor is not regularly estimated the authors consider that three months should be allowed between donations.

Medical Memoranda

Scabies in an Army Unit

It has been held that blankets and clothing play an important part in the spread of scabies in the Army. Mellanby (1941a), on the other hand, from recent experiments with volunteers and other considerations, believed that fomites are unimportant in the transmission of scabies, and that many cases are acquired on leave, from wife or child.

The following is an account of 39 cases seen in one unit during 7 months. Of these, 36 were carefully investigated in an attempt to find out how the disease was acquired. The number of cases is small, but the series is thought to be interesting in that the conditions in the unit remained unchanged during the period and the circumstances were such that men rarely slept out except when they returned home on privilege leave. Week-end leave did not complicate the picture.

THE INVESTIGATION

Our methods of control consisted of monthly skin inspections of the whole unit, inspection of each man when he returned from leave, and the immediate hospital treatment of each case when detected, together with disinfestation of bedding and clothing. When a man reported sick with scabies he was questioned as to possible contact with other cases both within and outside his unit, as to the date when he last returned from leave, whether he was married or single, about children, and as to the whereabouts of his home. Little evidence was obtained of spread within the unit by means of blankets. In only 2 cases was there any connexion with another case within the unit (i.e., sleeping in the same hut or guard-room). In several cases it was evident that scabies had been present for at least 14 days before being detected, and yet skin inspection of other men of the hut failed to disclose further cases. The cases occurred at an even rate throughout the 7 months; there were no little epidemics confined to one hut or one company such as readily occur in pediculosis, which is undoubtedly spread by fomites.

Direct evidence of scabies acquired on leave was difficult to obtain. To contract scabies is considered by the men to be a disgrace, and as they are not willing to admit that their families could have the disease, great tact is necessary in questioning them. In 5 instances, however, clear evidence that there was scabies at home was obtained. It was found that out of the 36 cases 14 (39%) developed the condition within a week, 2 (5.5%) within 2 weeks, and 5 (14%) within 3 weeks of returning from leave. Thus 58.5% developed scabies within 3 weeks of returning. The leave rate during this time was about 6.4% a week, so in a normal group of men only 19% could have been expected to return from leave within 3 weeks. If Mellanby's views are correct a higher proportion of married men in the series was to be expected: actually it was found that 74% were married. In a control group of men from the unit only 51% were married. The towns where the men had been on leave were those of the industrial North and Midlands. No particular town was found to be associated with an undue proportion of these cases.

Mellanby (1941b) estimated the incidence of scabies in the general population as about 25 per 1,000. In the period under review there were 39 cases, and 1,700 men went on leave and were in contact with their homes. If 60% of cases are due to infection from home then a rough approximation of a scabies incidence in the general population of 16 per 1,000 is arrived at. If it is believed that a higher proportion than 60% are infected at home, then the figures rise to 23 per 1,000. When, therefore, the incidence of scabies in the unit is compared with Mellanby's figures for the general population it is not inconsistent to hold the view that the majority of cases were infected on leave.

CONCLUSION

Consideration of the cases of scabies occurring in an Army unit over a period of 7 months suggested that the majority of these men were infected from their homes while on leave. It would seem that blankets and clothes do not play a large part in transmission, and that fairly prolonged and intimate contact with another case is necessary to acquire the disease. The disease cannot be reduced much further in the Army at home until the problem of civilian scabies is vigorously tackled.

Reviews

CARDIOLOGY

The Principles and Practice of Cardiology. By Crighton Bramwell, M.D., F.R.C.P., and John T. King, M.D., F.A.C.P. (Pp. 509; illustrated. 35s.) London: Oxford University Press. 1942.

This volume on the *Principles and Practice of Cardiology* embodies the conception that medical thought has developed along different lines on the two sides of the Atlantic. Whereas laboratory methods have been progressively developed in the U.S. and Canada, clinical observation has always dominated the British outlook. Accordingly Dr. Crighton Bramwell has dealt with general problems, such as the physical basis of clinical signs, clinical methods, and principles of treatment. Dr. J. T. King holds that a regional classification of disease is now obsolete and that the only satisfactory basis is aetiology; he has therefore dealt with the various aetiological forms of heart disease. How far this is a natural subdivision and in what measure it lends itself to a profitable approach to cardiology will be very much a matter of opinion. It is true that each of the two sections of the work bears the stamp of a certain outlook on cardiology, but some of the consequences of this subdivision are hardly fortunate. Thus disease of the pericardium is considered at four places: in the first few pages under symptomatology, further on under heart sounds and murmurs, later in terms of rheumatic heart disease, and finally in a section on miscellaneous forms of pericarditis.

In the first part of the book Dr. Bramwell has throughout kept in mind the importance of envisaging the manner in which physical signs are produced. An excellent chapter, embodying many of the author's original contributions to the subject, is that on the pulse; other valuable sections are those on blood pressure and athlete's heart. In the latter are included the author's observations on marathon runners; in this also are enunciated the principal dangers of athletics—undue and competitive strain in growing youths, physical strain after recent infection, and frequently repeated severe muscular exercise. Reference in the section on blood pressure to the work of Treadgold demonstrates the relative insignificance of low blood pressures: a systolic blood pressure below 100 may be compatible with perfect health, as many as 3% of fit pilots being hypotensive. This finding is in accordance with the established actuarial fact that a better expectation of life exists among those with subnormal blood pressures than among those with average blood pressures.

In the second part Dr. King has shown an individual outlook upon many of the problems connected with the aetiology of heart disease. Particularly interesting is his view that rheumatism and chronic infections such as tonsillitis play an important part in the production of coronary artery disease and hypertension. While most clinicians could recall suspected examples of rheumatic involvement of the coronary arteries or of coronary thrombosis almost certainly related to infection, most would also demand stronger objective evidence of the general relationship than the statistical evidence here advanced or the personal impressions from case histories. However, speculation on this point may be not only diverting but ultimately valuable. The sections on bacterial endocarditis and coronary thrombosis are especially worthy of mention. The differences between coronary obstruction in middle and in later life as regards causation and prognosis are particularly well brought out. Dr. King has illustrated his work with many fine photographs of morbid anatomical specimens, and carefully chosen bibliographies augment the value of the text. In the chapter on rheumatic heart disease an excellent account is given of the evolution of mitral stenosis, but many readers will be surprised at the doubt expressed as to whether or not auricular fibrillation adds significantly to the circulatory embarrassment. The frequency of associated heart failure might, apart from strong experimental evidence, be taken as proof of the detrimental influence of this arrhythmia.

This Anglo-American textbook of cardiology, designed as it is upon a somewhat artificial basis, will nevertheless claim attention by virtue of the integrity and thoroughness of the authors and the intrinsic value of their various contributions.

SCHOOL MEDICAL AND CHILD WELFARE WORK

A Handbook for Assistant Medical Officers of Health on Child Welfare and School Medical Work. By F. J. G. Lishman, M.D.(Hyg.), D.P.H., D.L.O. (Pp. 63. 6s. paper boards.) London: H. K. Lewis & Co. 1942.

This handbook was first written for the guidance of assistant medical officers engaged by the Devon County Council to cope with the additional work caused by evacuation. It is designed for those taking up school medical and child welfare work for the first time. There are 20 pages of text describing the ordinary work of an assistant school medical officer, and the rest of the book consists of model leaflets of advice to parents, model forms used in school medical work, and Dr. Lishman's own scheme for the assessment of nutritional conditions. The first section, on co-operation, pays due tribute to the work of health visitors and teachers, without whose help no assistant medical officer can hope to be successful. The working of a maternity and child welfare centre is then described and emphasis laid on the fact that the primary object of the centre is educational. The section on the school medical service contains a detailed description of how to carry out an inspection in a school and how to deal with children who have defects or are "exceptional."

The advice given is thoroughly sound and practical, and only minor points call for criticism. In the section on school work it would have been advisable to draw attention to the importance of investigating the regularity of school attendance of individual children. A warning should be given that certification of mental defectives can be done only by medical officers who are specially approved. It is almost impossible to make a book like this up to date in existing circumstances, and it should be noted that derris root, recommended for lousiness, is no longer plentiful, and that some of the leaflets on feeding need considerable modification in wartime. The scheme for nutritional assessment is a sincere attempt to introduce some uniformity where probably none is possible, but it does serve as a useful guide to the examiner. This little book can be thoroughly recommended to those who are beginning child welfare and school medical work.

PREPARATION AND AFTER-CARE OF SURGICAL PATIENTS

Synopsis of the Preparation and After-care of Surgical Patients. By Hugh C. Ilgenfritz, M.D., and Rawley M. Penick, jun., M.D., F.A.C.S. (Pp. 532. 25s.) London: Henry Kimpton. 1942.

Lord Moynihan was wont to remark that surgery had been made safe for the patient and our task was now to make the patient safe for surgery. This laudable idea would appear to be the *raison d'être* of this book on the preparation and after-care of surgical patients. Urban Maes in a foreword writes: "It is obvious that much of the future progress in surgery will develop from closer co-operation between the scientific investigator and the practising surgeon." If we find in this volume chiefly an account of the results of such past co-operation as have a bearing on the care of patients both before and after operation, there are also some hints as to possible future developments. Well-set-out descriptions of pre- and post-operative management, such as we find here, will be not only of value to the house-surgeon just taking up his appointment but also a salutary corrective to many surgeons whose work may have become of so routine a nature that pre- and post-operative care have perhaps lost the relative significance which should be given to these all-important phases of surgical management. It is becoming increasingly realized to-day that the operation is but one event in the surgical treatment of a particular patient, and if this is obvious in such cases as thyrotoxicosis or intestinal or biliary obstruction, we are here reminded that it applies none the less to the surgery of the nervous system, the chest, or, indeed, any other region.

The book is of a suitable size to fit the capacious side-pocket of the house-surgeon: it contains some good line drawings and photographs and a useful appendix, with, among other things, an account of the newer chemotherapeutic agents, oxygen administration, and some tables of concentration of the blood constituents. Recent work such as the pre-operative use of vitamin B_1 (thiamin chloride) in thyrotoxic cases is included, and we may sum up by saying that here we have in convenient size an up-to-date and very useful account of the management of surgical patients, both before and after operation.

Notes on Books

The Natural Development of the Child is a difficult subject to write about, for to be natural is to be happy, and the happiest child is, like the nation, one with no particular history. So in order to write about the natural child it is almost inevitable that the unnatural or pathological must be quoted, if only to show what the natural development should not be. Dr. AGATHA BOWLEY has not escaped from this dilemma, but she has produced a readable simple book which should be of great service to parent and teacher. To the medical reviewer she seems best when she is on her own aspect of the subject—education—but then the medical reviewer may not be altogether competent to judge of this. It is curious how every now and then she reverts to the tenets of the psycho-analytic school in which she has evidently been trained, but when she does she is not very convincing and does not seem to be very convinced herself. The tracing of the accomplishments and difficulties of the child from birth to adolescence is well done, and the final chapter, on the effects of war on our children, is stimulating and suggestive. Dr. Bowley believes firmly in the need for a strong liaison between medicine, education, and psychology on sound child-guidance lines, and looks forward to these three sciences leading to a renaissance of happiness and opportunity for the child after the war. Her book is published in Edinburgh by E. and S. Livingstone at 8s. 6d. plus 6d. postage.

Dr. GEORGE WAY HARLEY'S book *Native African Medicine: With Special Reference to its Practice in the Mano Tribe of Liberia* is published in this country by the Oxford University Press at 20s. Over twenty years of West African experience have given Dr. Harley a close insight into the anthropology and ethnology of Negro Africa, especially throughout Liberia. Many thousands of natives passed through his hands, and he was ever on the alert to probe into the psychology of their rational and magical treatment of disease. The book deals largely with the extent to which the African native has been able to discover for himself successful methods of effecting cures. Dr. Harley's descriptions of the use of magic and fetishes are of practices which are too fanciful for serious consideration, but with his keen analytical mind he has been able to trace the underlying motive for many of the ideas about native witchcraft and the rather terrible deeds of secret societies. The author has compiled a good summary of diseases and a botanical list of plants used for herbal remedies; also a comprehensive bibliography of works on Africa. Anthropologists and medical men interested in tropical medicine will find valuable material in this book.

Preparations and Appliances

A DIRECTOR STIRRUP

Mr. E. T. BAILEY, M.B., F.R.C.S., surgeon in charge of fracture "A" department, Northern Hospital, Winchmore Hill, writes:

This stirrup has been designed to dispense with spanners for Kirschner wire gripping and straining and, at the same time, to act as a wire director. It is adjustable for width and can be used also with Steinmann pins.

It is made of 1/2-inch-diameter rounded metal, in two halves (Fig. 1), each consisting of a side-arm with an expanded head and two parallel cross-bars. One half has fixed to the outer side of the head a form of chuck, through which the Kirschner wire passes, to be gripped by a "bulldog" locking device with a wing-nut (B) of standard Whitworth thread. The head itself has a cone-shaped central aperture to guide the wire into the chuck. The cross-bars of this half are tubular, to receive the solid bars of the opposite side, which are locked after adjustment for width by a similar wing-nut (A) fixed on the outer cross-bar. The other half carries a similar but movable chuck which is slotted through the expanded head to end in a circular disk with a central 2-mm. aperture. Between this disk and the expanded head is a circular nut (E) for fixation of the chuck when used as a director, while immediately to the outer side of the head is a larger straining wing-nut (D), by turning which, after the wire is gripped, the whole chuck is drawn through the head until enough tension is obtained. Immediately below the head on each side the side-arm is perforated to take the pointed ends of a Steinmann pin up to 6 inches in length.

For Use as a Combined Director and Stirrup.—The stirrup is applied to grip the part firmly between the expanded heads of the side-arms, and is steadied by an assistant (Fig. 2). By means of the circular nut (E) the movable chuck is fixed after it has been protracted through the head to the required gripping interval, which may be reduced to as little as 2½ inches to hold the os calcis or tibia. A wire is drilled through the movable chuck straight into the bone, to emerge through the fixed chuck on the opposite side. In most cases the wire passes cleanly through, but should it catch on leaving the bone a slight movement of the side-arm is sufficient to cause it to engage in the conical aperture leading into the distal chuck. The wire is then gripped by tightening the wing-nuts B and C, care being taken to have the movable chuck in the position ready for straining (Fig. 3), which is accomplished by turning the straining nut (D).

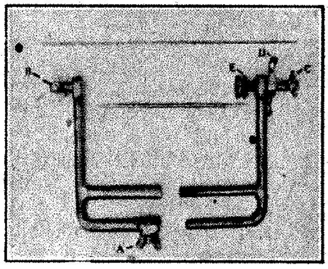

FIG. 1

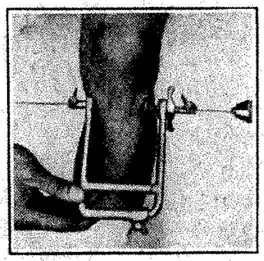

FIG. 2

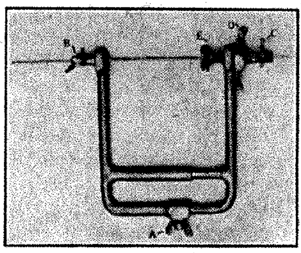

FIG. 3

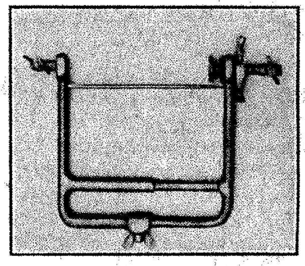

FIG. 4

FIG. 1.—A: Locking nut. B and C: Wire-gripping nuts. D: Wire-straining nut. E: Circular nut for fixation of chuck.

FIG. 2.—Wire director applied to the tibia.

FIG. 3.—Assembled with wire ready for straining.

FIG. 4.—Assembled with Steinmann pin.

For Use as a Stirrup Only.—The Kirschner wire is first drilled through the bone independently, and the two halves of the stirrup are threaded separately over the ends of the wire and locked together. Gripping and straining are then completed as before.

For Removal of Wire.—One half of the stirrup is detached, leaving the other half still gripping the wire for easy withdrawal.

For Use with Steinmann Pins.—The pin aperture of each side is threaded over the pin-point, and the two halves are locked (Fig. 4).

It is hoped that the instrument, while serving several purposes, will help to overcome the difficulties arising from the use of stirrups with an apparently endless variation in size of nuts, strainers, and spanners, due to differences in standardization. As each director stirrup is a complete entity, any slight variation in manufacture will not cause this inconvenience.

The stirrups are made by Messrs. Masters and Son, Old Kent Road, London, S.E., and have been supplied through the London County Council, to whose photographic department at the Southern Group Laboratory I am also indebted for the photographs reproduced.

CALCULATING FOOD VALUES

Messrs. Vitamins Ltd. (23, Upper Mall, Hammersmith, London, W.6) have just issued a "Food Value Calculator" (price 2s. 6d.) designed to simplify the evaluation of family and institutional diets in terms of the main nutrients. This ingenious device consists of two superimposed concentric circles of card, so arranged that one can be simply slid over the other, thereby revealing through appropriate slots the kind of approximate figures that dietitians and nutritionists often wish to have quickly at their disposal and almost as often have to do without—or at best elaborately to calculate for themselves. Incidentally, it manages to cram together very competently a mass of general information about the composition of many foods, including milk, butter, and cheese, cereals and bread, fruit and vegetables, eggs, fish, and meat. Conservative estimates as to average daily requirements are given for protein, calcium, iron (available), and vitamins A, B_1, and C.

PULMONARY DISEASE IN MINERS

There is still a wide belief outside coal-mining circles that the dust hazard of coal-mining is relatively unimportant, that anthracosis causes little incapacity, and that, in contrast to silicosis, it does not predispose to tuberculosis. The recently published M.R.C. report[1] on chronic pulmonary disease in South Wales miners is a most valuable contribution to this highly important industrial problem, and should go far to correct misconceptions and to provide evidence on which preventive action can be based. And it is fitting that the report should be issued at a time when much attention is focused on the reorganization of the coal-mining industry. The present volume, entitled "Medical Studies," consists of a report by the Committee on Industrial Pulmonary Disease, an extensive medical survey carried out by P. D'Arcy Hart and E. A. Aslett, and a pathological report by T. A. Belt (with assistance from A. A. Ferris). We are promised a second volume on environmental investigations within a few months.

It is pertinent to refer to the events that led up to the investigation. It had been recognized that in the coal-mining industry one class of occupation was comparable with the surface industries (for instance, quarrying and dressing of sandstone) causing silicosis—the driving of hard headings through strata composed of various kinds of rock. But the number of men engaged in this class of work formed only a small proportion of the total number employed underground. In 1936 the chief medical officer of the Silicosis Medical Board drew attention to the increasing claims for compensation made by coal-miners in South Wales: thus in 1933 there were 234 claims; in 1935, 398 claims. Moreover, the proportion of refusals rose from 23% to 52%. It was noted that a large proportion of the cases arose in the South Wales coalfield, and that by far the greater proportion of the increase was derived from the anthracite mines in this area. The increasing proportion of refusals appeared to be due to the fact that a disabling pulmonary disease existed among the miners which did not fulfil exactly the definition for silicosis laid down by the International Conference held at Johannesburg in 1930. At the request of the Home Office and the Mines Department the Medical Research Council therefore undertook to investigate the whole problem from the aetiological, clinical, and radiological points of view.

The medical survey involved the examination of 2,000 miners from 16 collieries, and of nearly 400 coal-trimmers from 4 coal-exporting ports. The entire population (560 persons) of one anthracite colliery was clinically and radiologically investigated, full industrial histories being taken. From the remaining 15 representative South Wales collieries (7 anthracite, 5 steam, and 3 bituminous coal) selected colliers were *x*-rayed only, again with full industrial histories. In addition, there were similarly investigated long-term workers from the surface screens at various collieries, and men occupied as hauliers or riders on the underground roadways at two of the bituminous coal collieries who had been exposed to the shale dust used for stone-dusting. The data obtained from this elaborate investigation were analysed in a most searching manner. There can be no doubt of the importance of the conclusions formed. Hart and Aslett offer a new radiological classification of the changes caused by dust in coal-miners. (Excellent representative *x*-ray plates are reproduced.) There are two main divisions: consolidation and reticulation. Consolidation is a composite category including discrete nodulation and various forms of conglomerate shadow, corresponds to the changes which generally go under the name of "silicosis" in coal-miners, and is seen in cases certified as "silicosis for compensation." But a substantial amount of pulmonary abnormality of the same type was also found in men still working underground. It is the cause of a serious amount of respiratory disability, taking the coalfield as a whole, although the affected men can often continue their accustomed work for some years within a limited range of effort. The greater part of this consolidation abnormality in the anthracite mines is found among the colliers. Its distribution is broadly correlated with the disposition of the differing ranks of the coals mined in this field: the highest is found in the anthracite mines in the western half of South Wales, the lowest in the bituminous mines of Monmouthshire; and there is a fairly gradual decrease in incidence between these extremes through the steam-coal mines.

No special emphasis has hitherto been laid on reticulation, a term newly coined. It is described as a characteristic non-nodular pulmonary *x*-ray change which may be associated with respiratory disability, but which does not conform to the criteria generally accepted as indicating silicosis for compensation purposes. It is a dust condition of occupational origin, as the appearances are very infrequent among the general population of the area. Reticulation is an earlier *x*-ray change than the well-known discrete nodular and conglomerate shadows, and it remains recognizable in these later stages. It represents in fact an essential part of the pneumoconiotic process leading to consolidation. Like the latter, it is found mainly among colliers. Its incidence follows a trend like that of consolidation, and is generally on a higher level than consolidation. Belt shows that this reticulation corresponds to a notable retention of silica (the greater part in the form of silicate) as well as of carbon, with the elaboration of reticular tissue throughout the interstitium of the lung. This "dust-reticulation" tends to impair the function of the lung by encroaching upon vital capacity and interfering with the elasticity of pulmonary tissue, thus contributing to the development of emphysema. Dust-reticulation is not necessarily progressive, but the grosser indurations of anthraco-silicosis develop on the basis of dust-reticulation. As dust-reticulation, and even the various stages of consolidation, differ from classical silicosis, it is suggested that the changes represented by both be included under the term "pneumokoniosis." Although no tubercle bacilli were found in the sputum of those in whom this examination was carried out, Belt shows that pulmonary tuberculosis tends to be so modified in colliers that it loses its identity and becomes merged with the pneumoconiosis. The combined effect constitutes a more or less separate and distinct disease; and the term "koniophthisis" is suggested to cover it. He also would like to see the term "anthracosis" replaced by the non-specific term "dust-reticulation." In the first place anthracosis has come to denote something harmless, akin to tattooing of the skin; and in the second place there is in such lungs a good deal of silica as well as coal-dust.

Hart and Aslett point out that even when reticulation is not accompanied by clinical disability its presence still implies the risk—considerable in certain mines—of the later progression to consolidation with its more serious accompaniment. It is not yet possible to say what is the cause of the changes described apart from the fact that dust at the coal face is responsible. So far it would appear that none of the actual methods and processes used in mining coal is the main factor in the incidence of either of the abnormalities in anthracite colliers, but they may be contributory. Therefore certain suggestions for change in mining procedure that might cause improvement are made by the Committee on Industrial Pulmonary Disease. The committee further recommends that "pneumokoniosis of coal-workers," when fulfilling the criteria of radiological change (including reticulation) and pulmonary disability, should be included with "silicosis" for purposes of compensation, and that not only underground workers but also screen workers at collieries and coal-trimmers at docks should be covered. Finally it points to the great advantage that would accrue from initial and periodic examinations of all coal-miners in South Wales. These examinations would make possible the transfer of men to more suitable work before they became unfit; they would facilitate the detection of tuberculosis and the removal from the mines of men in an infective stage; and over a long period of time they would provide a means of observing the effects on health of any preventive measures carried out in the mines. Although it is not so stated, we assume that an *x*-ray examination is regarded as an essential part of the initial and periodic examinations, and it should therefore be known how far miniature indirect radiography would lend itself to the detection of reticulation.

---

[1] *Chronic Pulmonary Disease in South Wales Coal-miners.* H.M. Stationery Office. (10s. 6d.)

The investigations are being continued, and further reports will be awaited with high interest. In the meantime two corollaries appear to follow from the findings and recommendations already published. In view of the established relation between dust-reticulation, or "anthracosis," and tuberculosis, it would seem wise to include active tuberculosis for the purpose of compensation. This would undoubtedly encourage the elimination of potential sources of infection from the mines. And, finally, some form of rehabilitation scheme involving vocational training for the partially incapacitated appears to be called for As T. W. Davies,[2] a tuberculosis physician to the Welsh National Memorial Association, has so graphically described, financial compensation, particularly when it is partial, fails to bring about the social rehabilitation of men who have been connected with mines all their life. Their plight, he says, is most distressing. And these men, at the present time at all events, represent an appreciable reservoir of man-power.

SCABIES

Scabies has always been one of the minor horrors of war, and it still remains with us in our present discontents. A fact, however, that has not been generally appreciated is that, although after 1918 its frequency diminished very much, scabies began to increase in 1936 while peace still reigned in Europe. It has undoubtedly increased more rapidly since the war broke out, but it is doubtful whether this can be attributed to shelter life and wartime crowding, for, as Kenneth Mellanby has pointed out, the disease has increased just as rapidly in areas where there has been little enemy action and where but a negligible portion of the community has ever lived in shelters. Other reasons must be sought to explain the increase. It is a little remarkable that scabies should be so difficult to control, for the causal organism is well known, comparatively large, and superficial in its attack. The central facts in the life history of the *Sarcoptes scabiei* are that the adult female landing on a new host immediately begins to burrow and lay eggs, which take just about a week to develop into adults. On emerging from the parent burrow they spend but a short time on the surface and then make burrows for themselves. Reproduction probably takes place both sexually and parthenogenetically.

The practical problem of the control of scabies divides itself naturally into two parts: the prevention of infection, and the provision of speedy and successful treatment. It is well known that the usual method of infection is by personal contact, and there seems no need for the contact to be particularly intimate. The chief point of contention among those who have experience of the disease is the importance of fomites in spreading infection. Since the last war the military authorities have always emphasized the dangers of infected blankets and have laid great stress on the disinfection of all fomites. According to R. M. Gordon and D. R. Seaton[1] spread by fomites is a risk, but it must be borne in mind that their work was carried out in animals with *Notoëdres*, not with *Sarcoptes*. Recent work by K. Mellanby,[2][3] which has been confirmed by several other observers, tends to show—and, in fact, well-nigh proves—that scabies is scarcely ever spread in this way. Volunteers have slept in beds previously occupied by heavily infected persons and have all escaped infection. (As, however, the accuracy of diagnosis of scabies in military circles is by no means above reproach, and as it is quite often confused with pediculosis, it will probably be wise for the Army to continue their present practice.) We must, however, seek elsewhere for the real reasons for the spread of the disease. Are there "scabies carriers"? The answer must be in the affirmative, for there is no doubt that there are many individuals infected with scabies who fail to exhibit the typical picture of the disease. In the first place there are insensitive persons on whose tactile nerves the nocturnal wanderings of the sarcoptes make no impression, and who consequently make no complaint of irritation, even though they may be heavily infected. But much commoner than these are individuals who have been infected only recently, and in whom the characteristics of the eruption have not yet properly developed. Scabies is not a disease in which infection takes place one day and in which the diagnosis can be readily made the next. It takes time to develop. This time varies a good deal in different people and depends to some extent on the personal habits of the patient. Those who pay close attention to daily ablutions undoubtedly delay the spread of the infection, though a daily bath will certainly not stop it. The time taken to establish the scabietic picture may, therefore, be anything from three weeks to two months. During that time the patient is an undoubted menace to his contacts. The menace ceases as soon as treatment is begun. The lesson to be drawn from these considerations is that as soon as one case of scabies is detected in a family, or in an institution such as a school, not only should that case be properly treated and all the contacts (e.g., other members of the family) be inspected, but in view of the difficulty of making the diagnosis in the early stages they should also undergo treatment. It is impossible to lay too much stress on the frequent inspection of individuals living a communal life or of those who are for one reason or another being sent to join a new community. This applies equally to members of the Forces, dwellers in hostels, or evacuated children. Any vesicle in the neighbourhood of the hands or feet should be an object of suspicion, for the sarcoptes may often be found therein, although not a single typical burrow may be discoverable, and on several occasions during the routine examination of children a single interphalangeal vesicle was the only lesion on the whole surface of the body and yet a sarcoptes was found in it. Had these cases not been detected they would undoubtedly have been serious sources of infection. As a counsel of perfection it is recommended that a skilled dermatologist should be available for consultation in all cases of any difficulty.

[3] *British Medical Journal*, 1942, 2, 1.

The second part of the problem is that of treatment. To be satisfactory the treatment of the disease must be speedily effective, easy to apply, free from objectionable odour and the risk of dermatitis, and there should be no relapses. "It must be admitted at once that the ideal sarcopticide still remains to be discovered"; in fact, it is questionable whether one has yet come to light more efficient than the time-honoured sulphur ointment. Sulphur in other forms can of course also be used. Among the new preparations which must be considered are benzyl benzoate, derris root and its active principle rotenone, and preparations of pyrethrum from *Chrysanthemum cinerariaefolium*. All these products have been thoroughly tested by Mellanby and his co-workers, and the following remarks are largely based on their conclusions. It appears that no substance has yet been tried which is superior to the old stand-by—the 10% sulphur ointment of the *B.P.*—or to the polysulphide preparation known as Marcussen's ointment or kathiolan. The only other sarcopticide which gives results in any way comparable is benzyl benzoate, of which a 20% emulsion in soft soap and spirit appears to be quite satisfactory. There is, however, a serious objection to this application in that it is liable to cause an intractable scrotal dermatitis. (The same objection seems to apply to derris root and rotenone.) Moreover, it is not very suitable for use at a children's treatment centre, for it always causes a certain amount of stinging, and if applied to a raw area or to septic burrows is extremely painful. As Dr. Dorothy Carter points out, it is difficult enough to get regular attendance at a treatment centre in any case; it is well-nigh impossible with a "burning lotion." One of the more prominent supporters of benzyl benzoate is Dr. N. D. Begg,[4] who has treated considerable numbers of cases as in-patients at the Eastern Hospital (L.C.C.). In-patient treatment of course gives the medical officer good clinical control; hence one is not greatly impressed with Dr. Begg's figures, which give the average duration of treatment in 157 cases as just over twenty days. There may be, however, an explanation for this in that his cases, being more severe than the average, were for that reason admitted to hospital.

Of the various preparations of sulphur other than ointment, which many object to on account of its messiness and its odour, dimethylthianthrene, which before the war was sold under the name "mitigal," is well spoken of by several observers, but it is expensive and now almost unobtainable. Gordon and Seaton had good results with tetraethylthiuram monosulphide in the treatment of animal scabies and recommend its trial in human cases. Sulphur lather and flowers of sulphur seem to be unreliable and no more free from the risks of dermatitis than ointment, and they also need more skill in their application. The conclusion that Mellanby has arrived at after careful study based on 1,500 cases is that the classical treatment of scabies, consisting of three applications of ointment after three baths, is quite satisfactory and efficacious. Even without the bath two applications of the ointment have yielded 100% cures. The lines upon which he looks for improvement are (1) the substitution of vanishing cream for the paraffin base, as both more pleasant to use and affording economy in the use of paraffin, and (2) diminution of the sulphur content of the application employed. For years many dermatologists have held that it is unnecessary to use an ointment containing 10% of sulphur, and in his experiments with the vanishing creams Mellanby finds that a cream containing only 0.5% sulphur is strong enough to kill most of the parasites. All are agreed that the treatment is most efficacious when administered by skilled personnel, but if this is not available sulphur ointment is the easiest and the most satisfactory when the treatment has to be administered by the patient or the patient's parents. On the whole the solution of the problem appears to be in the direction of more accurate diagnosis and not only inspection but treatment of contacts. There is no serious fault to find with the classical treatment of the disease.

HYPNOTICS, ANALEPTICS, AND MENTAL DISEASE

Sleep is a many-faceted problem. Only a conjunction of comparative biology, chemical physiology, electro-physiology, clinical and experimental neurology and psychiatry will suffice to give even an approximate account of the phenomenon we call sleep. Even with such diverse fields of knowledge to draw upon our understanding remains provisional. If there is a sleep centre, or, more correctly, a waking centre, what determines its rhythm, and of what nature is its own intimate activity? Sometimes pharmacological experiment will help to get to the root of a matter of this kind:- the tissues may be subjected to chemical substances introduced from without, and their reaction examined. It has been found that one of the effects of hypnotics is to damp down oxidation in brain cells; it is therefore possible that one of the characteristics of the sleep process, and perhaps one of its fundamental conditions, is a lowering of metabolism in brain tissue, especially in those cellular regions upon which the occurrence of sleep most intimately depends. Variations in the temperature of a tissue are indicative of variation in the oxidation rate in it. Using this principle, Pick[1] has shown that the temperature of different parts of the brain may be made to vary by giving hypnotics, and in this way he has confirmed the differential locus of action of the latter. This was demonstrated in another fashion in Kieser's[2] chemical observations on the different concentration of hypnotic substances in different parts of the brain. Ether and paraldehyde cool the cortex more than the brain stem, and luminal has the reverse effect. The same delicate technique of the thermal couple which will register changes of temperature as small as 1/200th of a degree centigrade in the brain cells has been used by Pick to investigate the mode of action of analeptics, especially cardiazol. This has become of great importance in view of the mystery that still attaches to the *modus operandi* of cardiazol and convulsion therapy generally in the cure of mental disease. Pick found that cardiazol, pharmacologically antagonistic to hypnotics, increases the cerebral metabolism, sending the brain temperature up by 0.5° C. Moreover, this action is primarily in the brain stem, as is that of all other convulsants which have recently acquired a reputation in the cure of mental disease. Do mental diseases after all depend, as Mott suggested, on insufficient oxidation, but not, as he thought, in the cortex so much as in the brain stem? It is unlikely that an uncomplicated hypothesis of that sort will prove to be sufficient. Sleep and mental disorder may be similar, but they are not the same thing. They cannot both be the result of sub-oxidation and nothing more. Knowledge must go deeper and become more minute still. It must be acknowledged that Nature's laboratory in the many-functioned brain stem is more than a little intricate. We may take its temperature, but the physico-chemical processes that go on there remain, in spite of much brilliant work, a wonderland still largely to be explored.

ORGANIZED TREATMENT OF CANCER

Forty years ago there was only one method of treatment which could hold out any hope for the patient suffering from cancer. During the last 20 years, however, great advances have been made in radiotherapy, and for many types of malignant disease it has become the treatment of choice. At first the surgeons looked upon radiotherapy with scepticism, but once its benefits were proved there was a grave danger of the two methods of treatment being looked upon as rivals. In recent years, however, it has become more and more evident that each is complementary to the other. During the last ten years the members of the Radium Commission have been in a unique position to realize the truth of this statement. As a result of their experience they have issued a memorandum (see p. 48) which suggests the principles of a regional organization for bringing together the two types of treatment, and the necessary ancillary services into one team. With our present knowledge of the treatment of cancer, such a team must consist not only of physicians, surgeons, and radiotherapists but also of pathologists and physicists who have special experience in assisting in the treatment of malignant disease and must be able to attend the operating theatres, treatment rooms, and wards. The memorandum points out that it may be necessary for this team to be chosen from several hospitals in the same region, although, owing to the nature of the apparatus, the radiotherapy will probably be centralized in one institution. There may be some difficulty in deciding the size of the team. If the number of surgeons is too great there will be a real danger that each will not get enough experience to become proficient. For the same reason the team must serve an area containing a population of about 1,000,000, from which some 1,000 treatable cancer cases may be expected. The memorandum stresses the importance of proper "follow-up" departments and the necessity for accurate records. A valuable suggestion is made as to the administration of such a cancer organization—namely, that there should be an executive committee, with representatives of all the hospitals and bodies concerned in the area. Among other duties, this committee would choose the team which carries out the work. The publication of this memorandum is opportune, because recently the Ministry of Health asked local authorities to draw up instalment schemes under the Cancer Act, and many local authorities may find a memorandum from such an independent and unbiased source as the Radium Commission of considerable help to them. Copies of the full text may be had from the Secretary of the Commission, Westminster Hospital, S.W.1.

DICOUMARIN

Cattle which are fed on spoiled sweet clover hay develop a haemorrhagic diathesis, as a result of which bleeding may occur in practically any part of the body.[1] Common sites of bleeding are the ischial and thigh regions, the neck and shoulders, and the wall of the thorax, but it is rare in the parenchymatous organs. Haemorrhage is common on the serous surfaces, but less so on the mucosae. Affected animals are particularly liable to bleed to death after operations such as castration and dehorning. Focal necrosis of the liver is sometimes found post mortem, but it is doubtful if this is closely correlated with the haemorrhagic tendency or if there are any characteristic anatomical changes except those due to haemorrhage and anaemia.[2] The haemorrhagic tendency is due to a decreased coagulability of the blood, and Roderick[3] showed that this was associated with a diminution in the amount of prothrombin as estimated by Howell's acetone-precipitation method. The mechanism is therefore different from haemophilia, in which blood coagulation is delayed but prothrombin is apparently normal. It may be mentioned in passing that haemophilia has recently been described in swine.[4] Roderick's investigations were the mainspring of the cycle of discoveries which have culminated in the recognition of hypoprothrombinaemia as the cause of haemorrhage in jaundice and the newly born and have led to their effective treatment by vitamin K.

It is fitting that the latest of these discoveries should be the isolation of the active principle of spoiled sweet clover hay, which depresses the formation of prothrombin, as 3,3-methylene-bis-(4-hydroxy-coumarin)—to which we referred earlier this year.[5, 6] Despite its long name, this anticoagulant, which is coming to be referred to as "dicoumarin," is a relatively simple substance easily synthesized. It is cheap and it acts by mouth, and these apparent advantages over heparin have encouraged people to experiment with it in infective and non-infective thrombosis in man.[7] In practice considerable difficulties are encountered. The action is very variable from case to case, owing perhaps to insolubility and irregular absorption, a difficulty which may be overcome by parenteral injection of the soluble sodium salt. From experiments on dogs, Bingham and co-workers[8] believe that the maximum dose tolerated intravenously is almost certainly not much greater than 25 mg. per kilo and very likely less. In man single doses of 1,000 mg. orally seem to be safe,[9] but it is not known how soon or how often they can be repeated. Divided dosage of the order of 200 to 300 mg. a day has also been used in man; the coagulability of the blood may be considerably reduced in 3 or 4 days, and the effects must be followed closely to avoid overdosage. There is obviously much to be learned about methods of administration, and it is essential that the knowledge should not be too dearly bought. There is a latent period of 24 to 72 hours before coagulation is reduced, but once the drug comes into action the effects may last for 8 to 10 days after withdrawal. Overdosage leads to multiple haemorrhages, and the condition is improved only temporarily by transfusion and little, if at all, by vitamin K. The significance of the various laboratory data is not yet clear. Dicoumarin has much less effect on the ordinary coagulation, and it is essential that the knowledge should not be (prothrombin time), and it may lead to an apparent reversal of the coagulant action of the tissue extracts usually employed in these tests.[10] The apparent advantages of dicoumarin over heparin in the treatment of thrombosis have thus not yet been established, and there is more than a possibility that it may prove more dangerous and less efficacious than heparin. Townsend and Mills[11] are right in suggesting that experimentation with dicoumarin in man should for the present be limited to clinics with special haematological facilities and previous experience in this field.

SURGICAL ECONOMICS IN WAR*

BY

Brigadier C. MAX PAGE, D.S.O., F.R.C.S.

In the organization of the Army the important part played by the medical services in maintaining the health of the troops is generally recognized. The possibility of keeping large armies in the field without undue wastage is accepted as being one of the striking achievements of preventive medicine of this century. This is effected by preventive inoculation, sanitation, and personal hygiene, and these subjects remain a primary and essential responsibility of the Service. When other methods are looked for whereby the medical branch can conserve man-power, it is apparent that, broadly considered, the efficient working of every department of the R.A.M.C. conduces to this end, and each branch has its special problems. I propose to consider in detail the responsibility from the surgical aspect. I will not refer to the handling of battle casualties, but to the less obvious and dramatic saving of man-power which can be effected by the management of the individual soldier suffering from diseases or disabilities that turn up apart from fighting. The views I express are personal, and are coloured by my observations of the results of various surgical work carried out in the Army and Ministry of Health Service during the past few years. The ideas put forward are not original, and the actions, advice, and attitude suggested are already operative in many centres. They are set forth here with the prime aim of giving the medical officer new to the Service a basis of action suited to our present needs.

The General Objective

A dogmatic definition of the procedures that will achieve an aim, the successful pursuit of which must in the main depend on an attitude of mind, is by no means easy. In medicine agreement between a group of doctors on the treatment and disposal of an individual case is seldom a simple problem. In peacetime the propriety and expediency of various methods of treatment are allowed to range over a wide field. In war the urgent need for the prevention or limitation of disabilities and for speed and efficiency in getting men back to work after illness requires no emphasis, nor does the importance of retaining a man in his unit, so far as this is possible, once he has become a trained and useful member of it. If every medical officer realizes his personal responsibility in the matter and considers his actions and their repercussions in this light something will be achieved. I will discuss the problem from the point of view of the unit M.O., the M.O. in charge of a reception station, and the operating surgeon.

The Unit Medical Officer's Work

The unit M.O. has an important part to play in the scheme, although the wide dispersal of troops complicates his work in war conditions. His position in relation to the men of his unit may be compared to that of a first-class general practitioner to his patients or, perhaps more appositely, with that of a whole-time school doctor. By means of periodic inspections he should be familiar with the physical condition and have some knowledge of the psychological attitude of all the men in his charge. He should be fully acquainted with the details of their routine work and training, and should take an interest in their recreations and study their intimate living conditions. By taking an active part in exercises and training, the M.O. will learn for himself the strain to which the troops are exposed, and will so acquire knowledge that may assist in preventing breakdowns; he will also in this way more easily win the co-operation of the officers and the confidence of the men.

Turning to matters of detail, it will be the responsibility of the medical officer to see that the unit is not carrying men unfit for the duties it is expected to perform. It is uneconomic to retain men in a job for which they are unsuited from physical or mental causes. Cases of acute disease or serious injury should clearly be evacuated promptly as they arise to the proper hospital, the location of which should be known, and with which personal contact should be made whenever possible. If, in routine inspections, the M.O. should detect such defects as varicose veins, bubonocele, or deformed toes, he should not be in too great haste to send the man for a specialist's opinion. This caution should certainly be adopted when a man does not himself complain of a defect, and is able to perform his full duties in spite of it.

It is in relation to the minor disabilities of the serving soldier that the M.O. will have the greatest opportunity for conserving the strength of his unit. Foot troubles represent an important proportion of this group. Prevention in these matters is clearly better than cure. He should make full use of the chiropodist and see for himself that boots and anklets fit properly. He should order such modifications to be carried out by the unit boot repairer as are possible or desirable. It should be noted that if a man has a foot defect which has proved no handicap in civil life the provision of light boots may sometimes solve the difficulty. The opinion and advice of a near-by orthopaedic surgeon will often help him in this respect. The M.O. should see that cases of foot-strain or tenosynovitis due to over-intensive training are rested before the condition becomes chronic. It must be recognized that the company officer is responsible for the care of his men's feet, but the M.O. should not on that account fail to take his part of the responsibility. A certain number of minor injuries may well be treated within the unit, but if it appears that recovery would be more rapid under better-equipped conditions the man should be transferred to hospital. The same remarks apply to cases of pyogenic infection. Cases of palmar whitlow in particular are best treated in hospital.

When a man is sent to hospital, whether for treatment or for opinion, the importance of sending notes bearing on the case may be emphasized. The M.O. should remember that the patient's history sheet does not always reach the consultant, nor does all the information which may be helpful. Reliable observations on the man's past medical history and on his value as an individual in the unit may be of considerable importance to the consultant if a proper decision on his treatment and disposal is to be made.

The Reception Station M.O.

Under quiet conditions the reception station can form an important buffer against hospitalization. Men may be retained for 10 days in these stations if they are not in need of specially skilled nursing and are likely to be able to return to their units within that period. At this stage an opportunity for some minor surgery arises. Certain nominated stations are now equipped to carry out injections for varicose veins. The selection of cases for this procedure is important, and observations on this point will be found in the *A.M.D. Bulletin*. Recent knee injuries should only be retained when the evidence suggests that there is no gross displacement of the meniscus or serious tear of a ligament. The accurate diagnosis of these injuries is of great importance, and further reference to the subject will be found below.

Reception stations will receive a good many cases of fibrositis. For localized cases injections of 1% novocain will often prove helpful and can do no harm. Hot-air baths can be arranged with a little resource either by extemporizing electric cradles or by the use of a paraffin stove. Cases of acute tonsillitis and laryngitis should not be automatically sent for examination by an E.N.T. specialist when the acute symptoms have resolved: unless there is definite evidence of chronic disease the man should be returned to duty.

The Surgeon's Responsibility

The surgeon can conserve man-power either by the advice he tenders or by his methods of operative management. In the presence of acute disease and serious injury, where active treatment is imposed, one can only suggest the importance of early rehabilitation once the acute phase is past.

It is in relation to what may be termed "cold surgery" that surgical economy or extravagance can be practised. One does not ask the surgeon abruptly to alter his peacetime views on technique. One asks him, however, to be persistently critical of his methods, and to assess so far as possible whether by his operation he is rendering the soldier more fit for his job with the least expenditure of time, or whether the soldier could by some adjustment carry on an active life without it. The argument will be clearer if some practical examples are given.

---

* A lecture delivered at an R.A.M.C. Depot to a group of newly engaged medical officers.

Hernia.—A large number of hernias are being operated on in this country, and the results are not as good as might be expected. The proportion of recurrences is high, and the evidence available suggests that in many cases this is due to defective technique. An operation on a soldier or industrial worker for hernia, if effectively performed, should in general render him an A1 man. These operations should, therefore, be scrupulously carried out by an approved method and by an experienced surgeon. In the after-management of these cases graded physical exercises are valuable in restoring a man's efficiency in the minimum time. Cases of bubonocele due to direct hernia, certainly in men showing a pronounced supra-inguinal bulge, should not be operated on. The condition does not carry any risk of bowel strangulation and can be controlled with a truss. Though the wearing of a truss relegates a man to a "B" category it does not prevent him from taking a useful part in some branches of the Army.

Appendicectomy.—When this operation is decided on in the "cold" period the evidence leading to the decision should be carefully sifted. I have seen a good many men submitted to this operation on account of right-sided pain who have been found subsequently to have a stone in the kidney or a hydronephrosis. Removal of the appendix for what is termed "appendix dyspepsia" should not be undertaken too readily.

Varicose Veins.—I would suggest that a mild degree of this condition does not involve any material disability for Army life any more than it does for a civil occupation, and that, therefore, treatment might often be deferred until after the war.

Operations on the Feet.—It has been generally recognized that operations on the bones of the soldier's foot seldom improve his capacity or category. The practice of cutting the foot to fit the boot was long ago found to be unsatisfactory. The use of less drastic measures and the fitting and modification of footwear, so far as is possible in the Service, deserve more attention than they are given. If a man has "got on" in civil life with a minor or even a major foot deformity, it will be found better to avoid operation except in specially selected cases.

Derangements of the Knee-joint.—Troubles with this joint are the cause of a good deal of short- and long-term disability in the Army. This source of wastage will continue so long as the troops play football. The minor cases may be quickly restored by a short period of rest and pressure followed by progressive, active use of the limb. In the more severe, treatment without accurate diagnosis is little better than a gamble. It is essential to differentiate clearly between damage to ligaments and a cartilage tear and displacement. The taking of a careful history of the circumstances and mechanism by which the injury was caused is of great value here. Tears of a ligament are produced when the leg is in the extended position by forced lateral deviation or hyperextension. Displacements of the menisci are caused when the knee is bent and a rotatory strain is applied. Operation is only justified if history and physical signs point to a tear or displacement of a cartilage. The site of the lesion should be determined with precision. It may be noted that the localization of pain and tenderness on the medial side is closely related to the position of the lesion, whereas with an injury of the lateral meniscus pain and tenderness are less well localized and are generally referred to the posterior aspect or centre of the joint. Routine *x*-ray examination should never be omitted or else cases of osteochondritis dissecans and other less common conditions will be missed. Operation duly carried out on a torn or displaced meniscus gives a high percentage of good results. If it is performed without a precise diagnosis being made and no gross lesion of the cartilage is found the outcome is usually unsatisfactory. In my experience the removal of both menisci (or parts of them) often leads to a joint which is not fully stable and seldom allows a man to be graded A1.

Fractures.—In these cases, which form so large a part of the surgeon's wartime practice, one can only recommend a critical attitude of mind. Does the method employed impede the speed of repair? Does it allow return of functional activity at as early a period as possible? Is everything done that can be done to avoid prolonged stiffening of joints in relation to the fracture? Most surgeons agree that overtraction or "distraction" of the fragments at a sensitive phase of the repair process is responsible for delay in union. How far alternative methods of treatment lead to better results must be determined by the individual. The reduction and fixation of a fracture are mechanical processes, and the problem is therefore subject to many solutions as regards the exact method employed.

Ear, Nose, and Throat Operations.—I am here on delicate ground and I will limit myself to a few remarks. Operations for the removal of tonsils and for deflected nasal septum very often result in a man being "Y" listed. There have been wholesale attacks on soldiers' tonsils in certain areas, whereas in other localities with similar military populations such operations are few and far between.

In conclusion, I would say that the views which I have sketched in a wide field may well be subject for discussion, and I must admit they often lack precision, but I would emphasize that my main aim has been to induce an attitude of mind which will assist our Service to do its full share in saving man-power and man-hours at the present time.

I should like to acknowledge my indebtedness to Major-General S. Kyle for advice in assembling these notes.

ORGANIZATION FOR CANCER TREATMENT

MEMORANDUM BY RADIUM COMMISSION*

The National Radium Commission has been established 12 years and during that time has gathered much information about radiotherapy and the organization of radiotherapeutic centres. The most important part of the work of such centres is the treatment of cancer, and of late years the Commission has extended its observation, wherever possible, to cover the whole field of cancer. As a result, the Commission has been impressed by the fact that the death rate continues to rise although the centres with which the Commission deals treat a constantly increasing number of cases, with a slow but persistent improvement in the number of patients who survive several years after treatment.

Some Remediable Factors

Among the remediable factors which contribute to this paradox are:

(1) *Late diagnosis.*—This is due to (*a*) unsatisfactory conditions under which many patients are seen for the first time—e.g., ill-equipped consulting-rooms and inadequate facilities for examination and note-taking; (*b*) inexperience of cancer on the part of some medical men who see only a few cases a year and recognize them only when they are far advanced; (*c*) ignorance and fear of the disease among the laity, which prevent the victim from seeking advice in the early stage.

(2) *Scarcity of beds.*—This is a factor affecting the treatment of all hospital patients, but it has a more evil effect on the cancer patient than almost any other. In most hospitals cases fall into three classes: (*a*) acute emergencies, surgical or medical, which are admitted instantly; (*b*) patients admitted by a member of the honorary staff and generally admitted to his own beds; (*c*) patients who need admission for investigation or for treatment that can be postponed. These are placed on a "waiting list" and often have to wait a very long time. Under this heading are included a large number of cancer patients, and while on the "waiting list" their disease steadily progresses.

(3) *Failure to select the most appropriate treatment for each case.*—This is due to the absence in most hospitals of any regular and organized system for consultation, before treatment is started, between the various specialists whose skill may be needed during that treatment.

(4) *Inefficient treatment in inadequately equipped centres.*—This is due to the natural ambition of every hospital to carry out all kinds of treatment, and want of co-operation between medium-sized and small hospitals to build up joint centres in those specialties in which the needs are more elaborate than their means allow.

A Cancer Organization on a Regional Basis

The National Radium Commission puts forward the following suggestions for the organization of the treatment of cancer on a regional basis.

General.—The precise form of the administrative arrangements on which a cancer organization should be built up must depend in great measure on the general arrangements for the post-war hospital service which the Government has promised.

---

* Owing to shortage of space the memorandum has been abridged.

While the outlines of these arrangements have already been announced, the details remain to be worked out, and accordingly it is not at the moment practicable to do more than assume that the arrangements will leave room for a cancer organization in which the various hospital authorities and other bodies concerned will play their part. The executive of such an organization should be in the hands of a special Cancer Committee. A whole-time Director of the Cancer Organization should be appointed, although it might be advisable to allow him private patients within his own hospital but not outside it. The choice of the director must depend on the man rather than on his specialty: he must clearly have a wide experience of cancer and should be one of the specialists engaged in the work of the organization. It is important that his position at the headquarters hospital should be assured, that he should be able to meet the members of the honorary staff on equal terms, and that he should be in full and effective control of the arrangements made for carrying out treatment.

The functions of a cancer organization are: (1) To put before the public those facts about cancer which ought to be generally known. (2) To secure the diagnosis of cancer at the earliest possible stage of the disease. (3) To secure prompt and adequate treatment of every case. (4) To improve established methods of treatment and devise new ones.

The area to be served should be of such a size that not fewer than 1,000 cancer cases are treated in a year. Such a number can be expected from a population of about a million, and this should normally be the smallest number of people for which a cancer organization should be established. This number of cases is necessary so that (1) each member of the medical team shall see a large enough number of cases to become expert; (2) the available radium and x-ray apparatus shall be used to capacity; (3) each type and site of growth may form a group large enough for statistical analysis in a few years.

The staff, besides the whole-time director, must include many specialists with all the assistants they need. Physicians, surgeons, E.N.T. surgeons, gynaecologists, radiotherapists, pathologists, radiodiagnosticians, and physicists must all form part of the team, be readily available, and meet in frequent consultation. As the work of the cancer organization must continue without interruption more than one specialist of each type must be on the staff, but most of them would probably devote part only of their time to the work of the cancer organization. It will be necessary for the radiotherapists, physicists, and pathologists to be wholly engaged on the work of the organization. Care should be taken that each specialist deals with enough cases to ensure that he becomes expert.

The housing of a cancer organization, in view of the staff requirements mentioned above, will almost certainly have to be in, or in close association with, one or more large general hospitals. One such general hospital would in most cases form the headquarters of the organization, and at that hospital it is desirable that a special block or department should be devoted to the work. The segregation of the cancer work makes the team more "cancer-minded," leads to an increase in efficiency, and facilitates better record-keeping. In few cases, however, will all the work of the organization be able to be done in one hospital, and arrangements will have to be made to utilize the facilities of several hospitals; in that case one or more members of the staff of each hospital concerned would be appointed as members of the team working the cancer organization. Provided that satisfactory arrangements are made for full consultation, effective co-operation, and perfect co-ordination, much of the work might with advantage be decentralized.

The arrangements for diagnosis present many difficult problems to be overcome. General medical practitioners will have to be taught to be "cancer-conscious" and persuaded to send promptly to the cancer organization all patients in whom any symptom calls for investigation. For this purpose it may be desirable to have arrangements for diagnosis at several or even at many hospitals in the region. Such hospitals must be well equipped for diagnosis and must be visited at regular intervals by members of the team who are capable of deciding whether the patient should be sent to one of the hospitals where treatment can be undertaken. Lectures should be arranged having for their object the encouragement of patients to seek advice early.

The treatment of cancer in any patient should be undertaken only after consultation between members of the team. At such a consultation the treatment of the individual should be planned, even though modification may be needed later. Although in some types of cancer the consultation may be a formality, nevertheless it provides an opportunity for the members of the team to review methods of treatment from time to time and for discussion. The treatment having been settled at consultation, it is then carried out by one of the specialists of the team, and at appropriate intervals or at the end of the treatment the patient is again seen in consultation.

The physicians of the organization will of course play their part in the diagnosis and treatment of cancer, but they should also be able to give much help in other ways. The recognition of metastases, the study of general reactions to treatment, the prevention and treatment of complications, and the supervision of the health of the workers with radium and x rays should all be done by physicians with special experience of these problems.

Treatment by surgery might be carried out at several of the hospitals taking part in the cancer organization, but it is essential that it should be done only by the surgeons of the team (who have special experience of the operations needed) after consultation with the radiotherapist. The surgeons must be provided with all the equipment that will enable them to do their work properly.

Treatment by radiotherapy will always have to be concentrated, if not at one, at most in very few, of the hospitals taking part in the cancer organization. The radiotherapist should be in full charge of all radium and x-ray therapy of the organization, though it will be necessary for him at times to work with the help of the surgeons. The radiotherapist should have at his disposal at least one gramme of radium so that he may in every case have available the containers best suited to it. He should have not fewer than two deep x-ray therapy sets so that if one breaks down treatment will not be interrupted. In an organization dealing with 1,000 or more cases a year he will need four or five tubes in constant use, in addition to those needed by the physicist. The organization of a radiotherapy department has been dealt with in a separate memorandum.

The pathologist plays an important part in the work of the cancer organization, and it is desirable that each organization should have at least one pathologist working for it. If the clinicians are to have as much help as can be given by a pathologist he must be familiar not only with all forms of cancer but with the habits of mind and methods of work of all those engaged in the organization. His duties will include the examination of material removed at biopsies to help in making a correct diagnosis, blood examinations and the examination of exudates, and bacterial examinations in patients with secondary infections; he should also be available to perform necropsies on patients who die, so that causes for the failure of treatment may be ascertained and important facts gathered about methods of spread, etc. If the work of the organization is carried on at more than one hospital, the pathological laboratory may conveniently be at only one of these, but the pathologist should be in personal contact with all members of the team.

Radiodiagnosis is necessary not only for the diagnosis of cancer but at many stages in the treatment and in the future follow-up of the patient. At every hospital where any part of the work of the cancer organization is done there must be an efficient radiodiagnostician with modern apparatus.

Physicists play an essential part in the work of any radiotherapy clinic. Their help is needed in the planning of radium appliances and the estimation of the dosage delivered. This work involves calculations which physicists are specially trained to do. X-ray therapy apparatus needs constant supervision and calibration, and depth-dose charts under many varying conditions are needed. Radium containers have to be tested frequently for leakage and examined for defects, and it is convenient for the physicist to be made custodian of the radium. He should be allowed facilities for research, be provided with a well-equipped laboratory and well-fitted workshop, and should have a whole-time mechanic. The setting of every patient each time he is treated should be done by one of the radiotherapists or under his direct supervision, but the physicist will frequently be needed to aid in beam direction and to see that patient and staff are adequately protected from stray radiation.

The beds for the organization should be set aside for its patients, and in large hospitals are best provided in a special block in which the x-ray therapy plant is situated and radium treatment carried out. There must be a large enough number of beds to make sure that no case is kept waiting for treatment. Some of these beds, for the surgical treatment of patients, may conveniently be in hospitals where no radiotherapy is done but where the surgical and gynaecological members of the team do their cancer work. Not fewer than 75 beds will be needed for the cancer organization.

The follow-up of cancer patients after treatment must be thorough and persistent. The patient should attend at regular intervals and should, wherever possible, be seen by those members of the team who originally planned the treatment. To save patients unnecessary travelling it may be possible for some follow-up work to be done at those hospitals where arrangements for diagnosis only have been made. All cancer patients should be followed up for at least 5 years, though much may be learnt by following them up for 10 years or even more. It is not enough that patients should be given an appointment to attend: arrangements should be made so that any patient who does not keep his appointment receives a reminder of it. This must be repeated until the patient does attend or until a report is obtained from some medical man who has examined the patient. For the purpose of this follow-up it is essential that there should be a system of visiting patients, and this can be done best by hospital almoners or public health visitors.

The records of a cancer organization must serve three purposes: (1) to record the patient's condition from time to time so that an estimate may be made of the changes that have taken place in the disease between his visits; (2) to provide accurate records of the treatment to act as a guide for further treatment when needed; (3) to provide a basis for statistical analysis of the results obtained by treatment so that the team may know where improvements are needed and in what direction they should be attempted. For these purposes it is essential that there should be a special case paper for the cancer organization which should be independent of the ordinary hospital in-patient case paper. It should be of a type that is uniform throughout all the hospitals taking part in the work of the cancer organization and the main file should be kept at the headquarters. Clinicians should always be provided with clerks at each clinic. The physicians' findings and conclusions, the pathologist's and radiodiagnostician's reports, the account of operations performed, and full details of any radiotherapy given should all be entered in their proper places. Statistical analysis cards should be prepared for every patient.

FEEDING OF INFANTS IN WARTIME

ADDRESS BY LORD WOOLTON

Lord Woolton, Minister of Food, attended the annual general meeting of the National Baby Welfare Council, held in the Great Hall of B.M.A. House on June 26, and gave an address on the feeding of babies in wartime.

He said that the proper feeding of the nation's children was one of the first tasks to which he addressed himself on taking office. He had the good fortune to have Lord Horder and Prof. J. C. Drummond as scientific advisers. The malnutrition which followed the last war was vividly remembered. It was obvious only to a comparatively small extent in this country, but on the Continent it took a terrible shape. The rising generation was left with physical defects and abnormalities, and often with a mental twist which had played no small part in fomenting trouble during the intervening years. He determined that any repetition of such a tragedy should be prevented in this country, even, if necessary, at some sacrifice on the part of the older people.

The first step was a baby's ration. The baby was allowed the same quantities of butter, cheese, sugar, jam, and (until lately) tea as the adult. No doubt the child in his first year ought not strictly to want these things, but it was right and proper that the mother, particularly the mother who was feeding her child as well as herself, should have food for both. The first claim on the milk supply was for pregnant women and young children. If the parents could pay for it, payment should be made, but if they could not pay they must have it all the same. The issue was not the financial position of the parents but the physical well-being of the child. Child priority in milk supplies could not have been carried out but for the generous help of America. Large supplies of powdered milk were in the United States ready to be brought over to this country, so that next winter adequate supplies of milk were ensured for infants, school children, and mothers. Orange juice also was being sent over from the U.S.A. in sufficient amount to ensure a supply for all babies next winter. The other foodstuff which gave special concern was eggs. These had been in short supply, but the children had had four times as many as the adults. He added that the restrictions were not the greatest difficulty of the Minister of Food; his greatest difficulty was the variability of the situation. He never knew which cargo was going to be sunk by a submarine, nor from what part of the world this country was going to be cut off. But whatever the circumstances, the good will of the public was behind this policy of looking after the children first. It was not sentimentality, it was statesmanship.

In reply to questions Lord Woolton said that the new milk organization he was setting up would go closely into the question of standards. He promised to consult his medical advisers on a suggestion that there should be extended to women during the ante-natal period the same facilities for obtaining cod-liver oil and orange juice as were available for infants. Other suggestions from the meeting were that the growing of parsley, said to be rich in vitamins and easily grown, should be encouraged, and that more consideration should be given to the value of butchers' offal, such as liver and tripe, for young children.

An address was also delivered by Mrs. Drexel Biddle, wife of the American Ambassador to the Allied Governments in this country, who suggested a scheme whereby concentrated foods for the relief of the civil population of the occupied countries would be taken in the vanguard of the troops of the United Nations on the opening up of a Continental front.

In the annual report adopted by the Council it was mentioned that an investigation had been undertaken into the spread of infectious diseases in day nurseries and nursery schools and classes. A suggestion has been made that there is an increased incidence of such infections through these channels, or that the infections occur at an earlier age than would otherwise be the case, the sequelae and complications being correspondingly more serious. No substantial evidence was found to support the case against the admission of pre-school groups to communal life in properly constructed and well-administered nursery centres.

Reports of Societies

DELAYED UNION OF FRACTURES

At a meeting of the British Orthopaedic Association held in Liverpool on May 29 and 30 under the presidency of Mr. G. R. Girdlestone (Oxford) there was a discussion on delayed union of fractures. Most of the speakers remarked on the impression generally held that delay in union is commoner than formerly; many of them mentioned the difficulties of the statistical approach, first of all in deciding upon a standard of "union" in the consideration of the time factor, and in comparing fractures of the same bone due to different types of violence. There was agreement in stressing the evils of late reduction, of distraction, and of infection.

Mr. G. Perkins (Roehampton) differentiated between "union" when the fracture was solid and "consolidation" when this had progressed to the state of ability to withstand normal stresses. He emphasized the importance of functional restoration and the need for muscular activity from the outset of treatment.

Mr. R. Watson-Jones (Liverpool) and S./Ldr. W. D. Coltart, R.A.F., presented a detailed analysis of 500 shaft fractures of the femur and tibia treated in Royal Air Force orthopaedic units. The most important factors responsible for delay in the union of these fractures had been: (*a*) infection, which trebled the union time; (*b*) distraction of the fragments by excessive skeletal traction, which caused very marked indolence of the fractured surfaces and doubled the union time; (*c*) delayed reduction, late remanipulation, and in the case of the femur late bowing or re-fracture, which almost doubled the union time. In the absence of these delaying influences fractures united firmly enough for the removal of splints and plaster in an average time of 14 weeks. Union to clinical tests had often been present earlier than this, but immobilization had been continued in walking plasters until the stage of radiographic consolidation. The early resumption of weight-bearing in a walking plaster had been proved to be a delaying factor in cases in which minor angulation remained; the weight-bearing tended to increase the angulation momentarily, and thereby distract the fractured surfaces on the open side of the fracture. If it was recognized that union had been delayed by infection, distraction, late remanipulation, etc., and the period of plaster immobilization was extended accordingly, these factors were responsible only for slow union and not for non-union. In this series where complete and uninterrupted immobilization had been maintained there was not a single case of established non-union. In 8 cases early bone-grafting had been performed to accelerate the rate of repair, but in the whole series there was not one case of sclerosis of the fractured surfaces and established non-union, despite a high proportion of grossly contaminated and infected fractures: 10% of the cases had been invalided; 90% returned to duty.

Mr. B. H. **Burns** (London) believed that the more accurate anatomical position maintained in the modern unpadded plaster cast was possibly counterbalanced by the longer time that appeared to be taken in reaching union. Well-planned open reduction in selected cases offered perfect anatomical restoration with greater freedom of the soft parts.

Prof. **Harlan Wilson** (U.S.A.) believed that the type of initial violence might account for the greater time taken by motor-cycle injuries, where speed of impact was noteworthy. He believed that damage to the vascular supply of bone had great bearing on the time of healing. He remarked on the frequency of delayed union in cases of multiple fracture, which in consequence made greater demands upon the body's osteogenetic functions. His experience with the use of the Roger Anderson method of treatment found it subject to the same conditions and time of fracture healing as other methods.

Major **White** (R.C.A.M.C., Toronto) believed that the factors most likely to affect the rate of union were apposition of fracture surfaces with complete and continuous immobilization. In his survey of 120 cases of fractured tibia reduction was considered adequate when it was radiologically estimated that 75% of the fracture surfaces were in apposition. In 51 well-reduced and immobilized legs the average for union was 4¼ months; in 13 inadequately reduced or poorly immobilized cases it was 8¼ months. Bone grafting had resulted in union in 96% of the cases, but rehabilitation seemed to take longer than in those uniting without operation.

Mr. D. L. **Griffiths** (Manchester) made a determined plea for statistical inquiry by statistical methods. He had submitted to such inquiry 249 cases of fracture, with displacement, of both bones of the leg. Four definite conclusions were arrived at: (1) Open fractures heal more slowly than closed fractures; the two forming distinct groups. (2) Direct violence, (3) severe violence, and (4) inadequate apposition of fragments were all delaying factors. Figures indicated that only the grosser errors of treatment are important in delaying union.

Mr. F. W. **Holdsworth** (Sheffield), in a study of 399 cases of fracture of the leg, treated throughout by his own team, stated that 349 returned to their own work, 35 to modified work, and 15 had very poor function. Of 303 adults, 102 compound fractures united in an average of 16¼ weeks (the longest were 28 weeks—4 cases); the remaining closed fractures united in an average of 13 weeks. He stressed the need to concentrate upon end-results rather than upon the time taken to reach them. Continuity of treatment by one unit was the essential requirement. He and other speakers deprecated the late reduction occasioned by the slow movement of patients from one hospital to another.

Mr. R. I. **Stirling** (Edinburgh) discussed dietetic factors with particular reference to the important part played by vitamin C.

A Rehabilitation Centre

On the afternoon of May 29 the Association paid a visit to an R.A.F. Rehabilitation Centre by permission of the Air Ministry. Members were conducted round the gymnasiums, playing fields, swimming pool, etc. Mr. **Watson-Jones** gave a clinical demonstration at which he stressed the importance of carefully graduated muscle exercises, carried out initially under the guidance of the medical officer and later in the gymnasium under the control of a group of physical training instructors and masseuses; and the value of various outdoor games in which the competitive team spirit was encouraged. The meeting was then addressed by Flight Lieut. **Cantor**, who described the working of the centre and the importance of the patient's treatment being kept under the close supervision of the medical officer at all stages. Finally S./Ldr. **Dawes**, the commanding officer, said how important it was to re-create mental and moral fibre in addition to restoring patients to full physical fitness.

Amputations

On the second day of the meeting a discussion was held on amputations, based upon the different views held by surgeons in Canada and Great Britain. The former attitude was stated by Dr. **Le Mesurier** of Toronto. The Canadian preference for end-bearing stumps for leg amputations was founded upon the excellent results and superiority of this type, as compared with those depending upon lateral bearing in the socket of an artificial limb. The speaker's remarks dealt more particularly with Syme's amputation, which he was surprised to find so universally condemned in Great Britain.

Dr. R. D. **Langdale-Kelham** (Roehampton) explained the views of the limb-fitting surgeons for the Ministry of Pensions, remarking on the large number of Syme's amputations which were performed in the last war and which had been re-amputated at a higher level. Many of the patients had been unable to tolerate end-bearing for more than eight years, and of those who had had reamputation not one failed to express his gratitude at being provided with a stump which gave complete confidence. A particular advantage was the better appearance of the limb, which was of importance to a woman. Mr. W. A. **Cochrane** (Edinburgh) made a plea for further consideration by British surgeons of the advantages of Syme's amputation. [While the experience of the Ministry of Pensions is based upon an enormous amount of material, it is necessary to remark on the fact that the amputations carried out during the last war were by a great variety of surgeons, whereas the Canadian work has been done by a restricted group, as, of course, in recent years has been the practice of the Ministry of Pensions.]

The following brief communications were made: (1) Trans-trochanteric Fracture of the Femur, by Mr. **Norman Capener**; (2) Rate of Regeneration of Peripheral Nerves, by Prof. H. J. **Seddon**; (3) Fractures of the Femur, by Mr. W. S. **Diggle**; (4) Air Arthrography in Lesions of the Semilunar Cartilages, by Mr. C. H. **Cullen** and Dr. G. Q. **Chance**.

Correspondence

Social Medicine

SIR,—Prof. J. A. Ryle, in his stimulating letter (June 27, p. 801), defines social medicine as follows: "Social medicine is clinical medicine activated in its aetiological inquiries by social conscience as well as scientific intent, and having as its main purpose the education of professional and lay thought and the direction of legislation on behalf of national health and efficiency." This definition would, I feel, be bettered by deleting the limiting word "clinical" and by printing "medicine" with a capital "M"; for is it not largely because doctors have confined themselves to clinical (or bedside) medicine that the ultimate causes of disease have been neglected and the progress of preventive medicine delayed?

Social medicine is, in some part, clinical medicine, but it is also, and in greater part, preventive medicine, and in whole it is just Medicine with a capital M: the science and art of making our people healthy and of keeping them healthy. Here I offer another definition: "Social medicine is the science and art of Medicine activated and directed by the study of social conditions for the promotion of national health and efficiency."—I am, etc.,

Oxford.

R. McCARRISON.

SIR,—Prof. Ryle has developed the suggestive ideas of Sir Farquhar Buzzard in his Oxford address (June 6, p. 703), and has coined the term "applied aetiology" to describe the scope and functions of social medicine. Perhaps "applied physiology" would be a better term. In the same way sanitation might be described as applied bacteriology, for sanitary practice is the application of our knowledge of bacteria in keeping them out of our food and water and in removing them safely in our drains and dustcarts. A good deal of leeway has still to be made up in internal sanitation, which is that cleansing of bacteria from our homes and workshops and from our persons. But in the study of disease, and in tracking back its ultimate causes, we reach a point in our effort at control in which we pass from pathology to physiology, from the study of impaired or disabled life (disease) to integral and complete life (health). This extension of the field of medical study and practice is called "social medicine"—a rather vague term. Medicine has always been social; and we seem to put the word "social" in front of it when it achieves a more efficient degree of service. We might as well speak of social haberdashery and social grocery when they reach the chain-store development in supplying their commodities. Sir Farquhar Buzzard has truly said that medicine hitherto has been preoccupied with disease and is now turning more and more towards the study of health. What is meant by social medicine is really the medicine of health.

He has advised the reorientation of the medical curriculum so that the doctor may play his part in this new and wider medicine. This idea holds out the prospect of a redirected curriculum designed to give the student a new and total conception of his future work as a doctor and a training for that work. In this new curriculum the chair of social (or total) medicine should be the keystone of the whole system, supporting, and being supported by, all the other subjects; and the young doctor would begin his work informed as to the fullness of its scope, and trained to practise the medicine of disease and also the medicine of health.

The two subjects most closely related to the "health" work of the doctor are obstetrics and paediatrics. It would be difficult to say which is the more important; and indeed they both hang closely together. But paediatrics is certainly the most neglected in teaching, and offers the greatest opportunity of improvement in practice. Hitherto the medical schools have given the "young" subject paediatrics a small place in teaching and examination, a place far short of its importance in practice. On this the views of practitioners would be of great interest and value, and might assist in overcoming the conservatism of the medical schools and hastening reform. The mother, the child, and the home are the basal unit of our social structure. The family is the oldest, strongest, and best of human societies; and the health of the family is the centre and beginning of national health. The home is the place where vital problems and principles of sociology and medicine meet, and where social medicine can operate with great power; and it is the field of practice that belongs pre-eminently to the family doctor.—I am, etc.,

Edinburgh. CHARLES MCNEIL.

The General Practitioner and Research

SIR,—However long delayed may be the end of the present struggle, the essential need for co-operation in national and economic affairs in the post-war world has been fully established. The need for a like degree of co-operation between the general practitioner and what can broadly be described as the research worker seems to us to be just as necessary.

At present the wide experience of the G.P. and his intimate knowledge, extending over many years, of his patients, their families, and their ailments, which give him many advantages of which he is sometimes not fully aware, end with his retirement or death. We believe that a team of G.P. volunteers in co-operation with a laboratory team working at some specific problem—for instance, asthma, allergic diseases, endocrine disorders, etc.—could throw some light on many problems at present obscure. Such teams in different areas, under the general direction of a central body, would result in pooling the experience of many G.P.s and would, we believe, be of great value to the advancement of medical knowledge.—We are, etc.,

A. K. JAMES.
H. J. GIBSON.

The Planning Commission's Report

SIR,—The Medical Planning Commission is to be congratulated upon putting forward the interim report for survey and discussion by the whole profession. Those who have been interested in medical planning for many years will be impressed by the faults of omission rather than commission: this makes constructive criticism easier.

A broad definition might have been a complete service for the body and mind (and spirit) of every individual. Clause (*a*) should have added "and progress to a higher level of health." "Every" means of every age and every status. I would add a clause (*c*): (i) To aid research and so to advance medical science, and (ii) to promote the co-operation of doctors on the one hand and patients on the other.

Under "Discussion" the basis of the service on the family as the normal unit with the family doctor as the normal medical attendant has always been approved by the vast majority of the profession. As one who has advocated "co-operation" for over 30 years I am glad that clause 27 has been agreed.

I feel that there is some confusion in the whole report between the principles of building up from below and the "organization" from above. As an advocate of the former method I would put forward the following criticisms, which I hope are constructive. The Health Service Centre should be in relation to a small general hospital. Representatives of all branches of the services should meet here, forming local medical advisory councils, which councils should be referred to in all matters concerning the health of the district. From these should be elected representatives to regional medical advisory councils; from these again representatives to the advisory council to the Ministry of Health.

The local medical advisory councils are of the greatest importance. If they function properly they will direct or divert the creative intelligence of extreme individualism into the common council on the one hand, avert the danger of stereotyped or standardized methods, which will always tend to be imposed by higher authorities, on the other, give opportunities for the exchange of ideas and views and so help the advance of science, and, if one may tread into the political sphere, they are "rational democratic."

Satisfaction with or complacency with regard to the working and terms of the National Health Insurance Act appears to me worse than dangerous. The best that can be said is that this Act has done little positive harm. It has been negative as regards the progress of medical science. It has been of financial benefit to the members of the profession who have large panels. In 1911 I levelled many criticisms against it and also prophecies, most of which have been justified. At that time I opposed the Act as not worthy of the intelligent planning by the medical profession of this country; I put forward the alternative scheme based upon group practice at centres; I was ruled out of order. I have regretted since that I did not move amendments which could have been woven into its framework, now suggested over 30 years later.

One other criticism: I should like to think that more attention had been given to the psychological aspect, but I have endeavoured to restrict myself to fundamentals only.—I am, etc.,

Teddington. P. W. L. CAMPS.

SIR,—Having just read the interim report of the Medical Planning Commission in your issue of June 20, I feel I should like to offer certain comments.

The first is in connexion with paragraph 38. Surely the admission that certain corrupt practices in our present system are likely to continue in any other system we may envisage or attempt to carry out is as damning an indictment as it is possible to find. Are we then to admit ourselves defeated, before we even begin, in any attempt to better our ideals? Are we just to admit the presence of such graft and not try to do anything about it? No reform of any worth was ever carried out in such a tame spirit. Or is this merely a symptom of our gradual moral decline and softness? Why should we assume that we simply have not the strength of mind to eliminate these evils?

I do not admit the argument set forth in paragraph 39. Surely it should be possible to have men trained specially in medical administration who would be eligible for administrative posts. I understand that in Canada a doctor has to undergo special training in medical administration before he is eligible for such posts as medical superintendent of any large hospital.

Paragraph 48 says: ". . . We could not, if we would, start with a clean slate." Why not? The whole point lies in that "if we would." There seems to me to be a lack of punch in the statement. If we have the necessary will and the necessary perseverance, we *can* start with a clean slate. Indeed we shall have to by very force of circumstances. What is the use of thinking up half measures when we are going to be forced to go the whole way? No one can be so short-sighted as to imagine that the end of the whole scheme will not be a whole-time salaried medical service.

Paragraph 48 also says: ". . . What is wanted is the adaptation, augmentation, and reorientation of existing services. . . ."

Fine words which mean plainly a patched-up affair, rather similar to nearly all our voluntary hospitals. Cumbersome buildings with additions, alleyways awkward to run with dozens of inconveniences—these have also been "adapted, augmented, and reorientated" when many of them ought to have been completely rebuilt. The type of mind which has made these ideas is the type of mind which has been responsible for our policy in the pre-war years. Always patch and hope for the best. Let us have something new: it has to come anyway.

I feel that so many of the objections to the whole-time salaried medical service are based on a spirit of complete materialism. The criterion of a man's ability is being accepted—as it has up to now very often—as the extent of his income. Surely it should be possible for our profession to show that we judge men by the quality of their work rather than the size of the income. Indeed, until we can infuse this spirit into ourselves any scheme can fail.—I am, etc.,

Ledbury. GEOFFREY G. AIREY.

SIR,—I have been interested in medical planning for some years and have done some work in that direction; as a result I have eagerly awaited the interim report of the Medical Planning Commission. There were moments while reading the report when I felt that a bold and constructive progressive policy was being taken, but, alas! I was quickly disillusioned when I reached the paragraphs on "Immediate Proposals."

It is known to all that our present health services are uneconomic, lack integration, and are very unwieldy, to say nothing of the overlapping and duplication; yet the Commission after many months of deliberation proposes nothing more than an immediate extension of N.H.I. to include the dependants of the insured persons. To begin work with the object of providing and making available to every member of the community a complete medical service, and incidentally improve the working conditions of the medical practitioner, and then to do no more than propose the extension of N.H.I. is, I feel, evidence of moral cowardice.

There is little doubt among the many doctors I have discussed this matter with that the only service which can remove the existing defects and introduce the essential improvements is a 100% State Medical Service. As I expected, the usual "bogy" of bureaucratic control and the platitudes of free choice of doctor and the lack of initiative in safe jobs have been resuscitated, but they will deceive no one—certainly not the community who want a complete medical service, or the doctors who are prepared to work the scheme as whole-time salaried officials. What choice of doctor is there in the public health service, in ante-natal, child welfare, and school clinics, also in the hospitals, whether voluntary or public? In what way has bureaucratic control adversely affected these services? The chief criticism which can be made is their lack of co-operation with the general practitioner, and this is not due to bureaucratic control.

Then there is the usual loose thinking about the cost of a complete service. We are told that the country cannot afford it. At the risk of being accused by some of holding doctrinaire views, I maintain that the service would cost no more and probably less than the present uneconomic and patchwork system. The money could be raised by taxation and compulsory contributions, and the funds pooled so that the money could be distributed to regions on the basis of population. The cost of the present medical services (excluding workmen's compensation, environmental and cash benefits under N.H.I.) is about £150,000,000 made up as follows:

Voluntary hospitals	£16,000,000
State-controlled hospitals	£43,000,000
Municipal health services	£13,000,000
National health insurance	£16,000,000
Private practice	£60,000,000
Nursing services	£2,000,000

The money is derived from many different sources—e.g., charity, fees from patients, contributory schemes such as the H.S.A., insurance as N.H.I., rates as the block grants to public hospitals, and finally from taxes such as the State and municipal medical services. Surely it would not be difficult to employ an expert to work out a scheme for raising the sum of £150,000,000 per annum, the amount required for a State Medical Service for the country as a whole, especially as it is shown that the bulk of the money is not drawn from taxation.

It is axiomatic that national survival in times like the present depends more than ever before on the health of the community, and upon the health of the community depends the health of each individual. Yet in the most essential of all services the medical practitioner is not allowed the economic security which is guaranteed to teachers or civil servants. To preach health to the underfed and to those to whom medical services are not freely available, and to praise the doctor who "unselfishly" gives of his best when in reality he is being hampered by the impending fear of economic and social insecurity, is sheer hypocrisy. A nation's health is its greatest asset, so let us have the best possible service for the community and the best possible conditions for the medical and lay personnel who will unhesitatingly maintain the high standard so essential for its success.—I am, etc.,

London, E.10. A. ROBERT FOX.

SIR,—Careful perusal of the interim report of the Medical Planning Commission leads one to the conclusion that (in this Utopia?) the salaries of the greater part of the medical profession as well as those of innumerable lay officials are to be paid by the State; but it is not therein apparent how the State, either by taxes and/or rates, is to raise these enormous sums. Some enlightenment on this matter might be perhaps helpful.—I am, etc.,

Rayleigh, Essex. C. H. BATEMAN.

Treatment of So-called "Crush Syndrome"

SIR,—In June of last year we brought forward evidence to suggest that the approach to the problem of the "crush syndrome" had previously been from a wrong basis, and that the condition, including its renal manifestations, was the result, primarily, not of toxaemia, but simply of the loss of blood constituents into the injured limb the capillaries of which had temporarily lost their function. Applying this conception therapeutically, we argued that the primary principle of treatment should be to stop the limb swelling, or, if it was swollen, to reduce the oedema. This we achieved by applying positive pressure of 60 mm. Hg to the limb. We published details of two cases successfully treated on these lines (*Lancet*, 1941, 1, 780).

Strong experimental support for our theory has recently been furnished by Duncan and Blalock (*Ann. Surg.*, 1942, 115, 684). By compressing the limbs of dogs in a special clamp they have produced a syndrome similar to the "crush syndrome" of man, including shock and renal failure. Untreated, 18 out of 19 dogs died. But when the damaged limbs immediately after release from compression were enclosed in a pneumatic tube with a pressure of 40 mm. Hg 15 out of 21 dogs survived.

Further experimental work is clearly required, particularly to elucidate the mechanism of production of the renal symptoms We suggest, however, that there is now sufficient evidence to justify routine prophylactic treatment being standardized on the lines advocated in our article. If this view is accepted, first-aid workers should be instructed to bandage firmly the limb as soon as it has been released. Immediate treatment on the same lines should be carried out in hospital, either with the apparatus we suggested or some modification which fulfils the same principles.

The present lull in aerial bombardment in many districts offers a suitable opportunity for working out the requisite measures of organization.—We are, etc.,

The Middlesex Hospital, London, W.1.

Syme's Amputation

SIR,—Sir William Wheeler (June 20, p. 770) mentions the late Mr. R. C. Elmslie's advocacy of Syme's amputation. The operation which Elmslie devised and practised was a modified Syme's amputation, the essential points being a small heel-flap and a high division of bone just where it begins to flare out. The modern operation was designed to avoid the undue bulbousness and poor ground clearance of the old Syme stump, which rendered impossible the fitting of a neat, light, durable, and efficient prosthesis. With the newer stump this is easy, and, furthermore, the skid, which was inevitable with the older limbs and played havoc with end-bearing, seems to have been eliminated. The only trouble we have had with this operation, properly performed in suitable cases, has been, curiously enough, to persuade any firm of limb-makers, but one, to construct the correct limb.—I am, etc.,

H. JACKSON BURROWS.

Standardized Wassermann Reactions

SIR,—The letter of Dr J. L. G. Iredale and Dr. H. R. M. Richards (June 27, p. 804) suggests the possibility that other directors of approved laboratories may not be aware that, as they were informed in Ministry of Health memoranda dated April 4, 1941, and January 11, 1942, the special laboratory of the Ministry of Health for comparisons of serum tests makes and supplies antigens for Wassermann and Kahn tests, haemolytic amboceptor (rabbit *v.* sheep), and preserved guinea-pig serum for complement, all of which are carefully tested before issue. As regards the preserved complement-serum, an inquiry which I made a year ago of the laboratories approved for tests under the V D. scheme to discover if they were finding difficulty in obtaining guinea-pigs for complement elicited replies which suggested that a number of them must be using complement of poor quality, a more potent cause of indifferent results than is often imagined; this gave another reason besides the guinea-pig supply problem for pushing on with the production of preserved complement-serum. Each ampoule of this serum is from a pool of 100 mature (600 g) healthy boars, and is tested for suitability of titre and for freedom from native amboceptor and undue sensitivity to antigen; it is probably, therefore, of better quality than the complement used in most laboratories. It is preserved by Dr. Richardson's method as described in the *Lancet*, 1941, **2**, 696—I am, etc.,

London, S W 1 L. W. HARRISON.

SIR,—Three things used in the performance of the Wassermann reaction can be standardized—namely, the technique, the antigen, and the saline.

Unfortunately for the man doing the test, the complement, the amboceptor, and the red blood cells cannot be dealt with in this way. It must be realized that this test requires the whole of the attention of the pathologist, who should do every step of the test from start to finish. The deplorable habit of deputing technicians to do part of the routine work should cease if reliable results are required. Thus it is apparent that no one should perform Wassermann reactions for clinicians until he has received proper and adequate training.

Furthermore, I would tentatively suggest that this country be divided up into four areas, each with its central V.D. laboratory, part of whose function would be to check and be checked by other laboratories doing V.D. pathology. In this way I feel certain the standard of the performance of the W.R. and allied serological tests would be immensely improved.—I am, etc.,

London, E 1 I N. ORPWOOD PRICE.

Sterilization of Surgical Rubber Gloves

SIR,—In the technique section of Dr. W. J. Stuart's article on the sterilization of gloves (June 6, p. 694) he remarks upon his own particular method and upon that obtaining in conjunction with high-pressure sterilizers. He does not subscribe to the principle of inducing a primary negative pressure, and instances the effective difference through first and second exhaustings as shown from the tests of Sandford and Cookson. I am venturing to comment upon his own practice, with slight modification.

Admittedly in a partial vacuum of 24 in. Hg an unknown air content is contained. This void is static except for a slight circulation of heated air. The admission of steam produces rapid movement and the entire content is in a state of minus pressure equilibrium per gauge until zero is reached. On attaining plus pressure the volume is progressively constant, while the heat and weight factors are now variable. The hottest steam occupies the upper stratum, while the heavier and more saturated descends and forces below it the heavier atmospheric air content until ultimate pressure is attained. Thus in the volume we have a graded gravity weight content under compression—the warmed saturated air, being the cooler and heavier, is precipitated to the lowest stratum. This can be cleared by opening the valve on the conduit from the bottom of the chamber, allowing a free discharge of air and steam, for the space of half a minute. It may be questioned whether the same gravity condition would be effected without the primary vacuum. The answer is (this process applying particularly to the treatment of dressings, that with the primary vacuum the steam is attenuated and absorbed into every part and particle of the void, penetrating the most remote interstices of the fabric Without vacuum the steam would expand in an erratic course and bottle up globules of air within the fabric by a compression surround.

With gloves, however, conditions differ—we are concerned with surface sterilization, outer and inner enclosed. The outer presents no difficulty, the inner does Assuming an unwrapped glove to be deposited in an autoclave, and a vacuum induced, air blisters would be raised on the fingers as by blowing into them, external minus pressure producing the same effect as internal impulsion. It is impossible to say whether these blisters would be arrested in a state of compression or whether the air would be driven out; hence a primary vacuum is attended with that risk and not to be commended for this particular purpose. As Dr. Stuart explains, the gloves are contained in a canvas cover, and as the impulse of pressure steam would impress the surfaces tightly together he inserts a piece of gauze to prevent apposition of the surfaces My own idea is (and I don't know if it is really practicable) to draw the rubber gloves over common cotton ones. The surfaces would be kept apart more effectually and the fabric would serve as a conductor to the steam. Moreover the material would absorb any water precipitated by condensation, which, when formed, is not entirely evaporated but mixes with the chalk and resolves an undesirable cement content in the fingers.

Dr. Stuart remarks casually on the drying, and in his own practice it may be convenient to leave the gloves within the heated chamber for some time to complete evaporation. In hospital routine, however, the complete process would be effected rapidly. For this final rendering I incline to mechanical extraction by inducing atmospheric air through a cotton-wool filter at a tension of 15 in. Hg at seal, breaking down to 5 in. with the air current passing. I am quite in accord with the pressure and time factors Dr. Stuart stipulates.—I am, etc.,

London, E 7 J CHARLTON ROBINSON.

Complacency in Anaesthetics ?

SIR,—In reply to Dr. Atkinson's request (June 20, p. 774), I can furnish statistics for orthopaedic anaesthetics. In the orthopaedic department at Botleys Park during the last 18 months 2,000 anaesthetics have been administered for all types of case without a fatality. The standard technique employed is induction with pentothal up to 1 g., followed by nitrous oxide and oxygen. In the cases (about half) anaesthetized by me personally N_2O and O_2 are delivered from rotametres, reinforced when necessary (which is rarely) by cyclopropane. CO_2 is absorbed by a Water's to-and-fro canister, which I consider is the most efficient method of absorption generally available. This technique is simple, safe, and very pleasant indeed for the patient, as sequelae such as vomiting rarely occur.

I do not think the greatest "rag-and-bottle" expert could better these results from any point of view.—I am, etc.,

F G ETHIRAJ, B M., B.Ch , D.A.

Mass Radiography

SIR,—Dr. Lavelle in his letter on the above subject (June 20, p. 773) misinterprets me, and appears to have missed the real point of my recent letter (May 30, p. 678).

I am fully aware of the trend of development of miniature radiographic technique in this country, and that is the very reason why I wrote calling attention to the merits of the 5 in by 4 in. film method, which I believe will in the long run hold the field My main contention was that it would be a mistake to supply apparatus for 35-mm. work on a large scale and thereby establish standards which are not the highest.

One of the first essentials in any nation-wide scheme of mass radiographic survey should be the standardization of apparatus and technique, and that is why I disagree with Dr. Lavelle that existing apparatus should be adapted. As regards high-tension generators I do not agree with him that an output of 100 mA is enough if the best results are to be obtained; I would say that 200 mA should be the minimum.

Mathematics was never my strong suit, and I must confess that the "few simple calculations" which will prove that 76 mm. by 35 mm. film when enlarged will show greater photographic sharpness than 5 in. by 4 in. film are not immediately obvious to me; all the calculations I can think of lead to the opposite conclusion. In any event, one of the principal advantages of the 5 in. by 4 in. film is that it is suitable for direct viewing and does not require enlargement.

As to stereoscopic views, I am in entire agreement with Dr. Lavelle as to the unjustifiable expense of routine full-size stereoscopic films of the chest, but I do maintain that when it is purely a question of accuracy two films taken from a slightly different viewpoint are better than one. In miniature radiography the very slight extra expense of stereoscopic views will probably prove to be justified.—I am, etc.,

Hull. R. HERMON.

SIR,—The recent publications and correspondence on mass radiography appear to centre on the production of the required picture, with details of apparatus and organization needed for the purpose and the results to be expected from surveys. We do not suppose that there are any radiologists or chest physicians who would dispute the ability of such a procedure to disclose many cases of symptomless tuberculosis, and neither do we consider that, granted all the necessary staff and apparatus, the administrative machinery could not be devised speedily for its use. We do dispute, however, that these should be the sole criteria for launching a campaign among the general public to popularize mass radiography at the present time.

Mass radiography has become a scientific possibility, a short jump ahead of our social progress. This gap must be closed before the public are asked to submit themselves to a process which may mean social disaster to many of them. It is not possible for tuberculosis physicians or radiologists to say by a glance at a film whether a patch of infiltration is due to tuberculosis or not, and several weeks or even months may elapse before any confident statement can be made to this effect. What is to happen to the patient in the interval? Observation in an institution, substandard work, repeated attendances at a tuberculosis dispensary? Such procedures may mean the loss of the individual's employment, and in many cases this may happen when the patient is not suffering from tuberculosis at all.

If we could be certain that mass radiography would eliminate tuberculous disease and that only, then we might have some justification for pressing our claim on the grounds that serious spread of the disease has been prevented. But this assurance cannot be given. Consequently, it is our considered opinion that: (*a*) the State must grant social security to those found to be suffering from the disease and to their dependants; (*b*) those requiring observation must be safeguarded in respect of their employment; and (*c*) the principle of substandard work must be accepted for those under observation or suffering from tuberculosis. When these principles are accepted by the State, then the door will be open to mass radiography and the medical sociologist will have happy hunting. Until these safeguards are introduced we feel the public will be asked to co-operate in a scheme the pitfalls of which they do not realize. If the general public once realized the implications we feel they would demand security before submitting themselves to mass radiography.—We are, etc.

Oxford.

NORMAN ENGLAND.
F. H. KEMP.

Declining Population and Preservation of the Race

SIR,—In all the correspondence hitherto published on this important topic nobody has said that there is presumably an optimum, as opposed to a maximum, density of population for the British Isles. When Nazism has been defeated we may presumably look forward to a time when the bulk of mankind will be united under some centralized or federal form of government for purposes of social, economic, and military security. When that is achieved it may be possible to decide what size of population can conveniently and comfortably be accommodated in the various territories of the globe. Such a conception may seem hopelessly idealistic while the principle that might is right still dominates human action, but if we may assume for the moment that mankind were to become sane would it be essential or desirable that the population of these islands, for example, should be maintained at its present or an even higher level? It is well to remember that in the past the British stock attained a pretty high standard of achievement in divers directions with a population rather less than a third of what it is to-day. When we are in a position to consider our population figure with less emotion and without fear of being crushed by a numerically superior potential enemy, those competent to judge will be able to gauge, with some degree of accuracy, what our optimum population should be. Then and then only shall we be able to advise parents as to how many children they ought to have. Contraception has been cited as a primary cause of the decline in the birth-rate, but this is a preposterous argument. The fact is that many persons are shying away from parenthood for a variety of reasons, some worthy, others less worthy. Many less desirable means of avoiding parenthood exist and would be resorted to in increasing measure if contraceptives were abolished by law. A radical change of social values and, still more, liberation from fear are necessary before we shall see the return of large families—if, indeed, these are desirable.

One other matter has received only scant attention from previous correspondents, and that is the treatment of sterile marriages. Whether subfertility is actually increasing or whether the public is becoming more aware that something can be done about it is an impossible question to answer at present, but it certainly seems that in this country the laity are, generally speaking, more alive to the matter than the medical profession. Except in a few large centres organization for the investigation and treatment of sterile matings is sadly inadequate and out of date. Children, perhaps from specially desirable potential parents, are thus being denied to the nation. The Family Planning Association has made a small beginning in this direction, and the medical officers at its clinics are ready to give advice and help on sterility to any who need it. The usual procedure is to refer them to hospitals or specialists who are competent to deal with the many and complex problems involved; but in one or two provincial clinics facilities for investigation and treatment (including tubal insufflation and salpingograms, endometrial biopsies, seminal fluid examinations, artificial inseminations, etc.) are already available.—I am, etc.,

MARGARET HADLEY JACKSON,
Member of the Medical Subcommittee, Family Planning Association.

Crediton, Devon.

Treatment of Scabies

SIR,—Prof. R. M. Gordon and Dr. D. R. Seaton (June 6, p. 685) quote results of treatment of scabies with derris powder. The successful treatments were among Service personnel subject to discipline, but Forman (1942) in a series from a civilian out-patient department did not have successful results. Prof. Gordon and Dr. Seaton consider that proper supervision is therefore essential, and also that treatment dermatitis, especially of the scrotum, may occur.

May I quote the results of the treatment of 62 school children whose infection with scabies was discovered between Sept. 1 and Christmas, 1941. The lotion used was: derris 1 oz., soap flakes 2½ drachms, water 1 pint. This was applied by parents or guardians at home, with the aid of written instructions, 3 times daily for 4 to 5 days. In some severe cases the treatment was continued for 7 to 10 days, but only 1 boy developed any treatment dermatitis. No disinfection of bedding or clothes was done and no extra baths were given, except to patients showing secondary septic "scratch" dermatitis. (Some evacuee patients were unable to obtain any baths in their billets.)

Eight children were not seen again after the initial diagnosis and beginning of treatment. Infectious illness or truancy accounts for most of these. The remaining 54 cases were found to be cured on inspection 4 to 10 days after starting treatment, and the children were returned to school within 7 to 10 days of their initial exclusion. In my experience this represents a great shortening of the period of exclusion found necessary when sulphur preparations are used for home treatment.

Of these 54 children, 28 were still clear when inspected 3 to 4 weeks later. Fifteen failed to appear for further inspection and 11 were found to have relapsed. Of these 11, 7 gave definite histories of sleeping with infected relatives over whom the public health department had then no control.—I am, etc.,

Public Health Department, Worcester. MARGARET SPENCER.

Obituary

FRANCIS JOSEPH BIRKS, M.B.

Dr. Francis Joseph Birks, who died on June 19 at the age of 67, was for many years one of the leading general practitioners in Sheffield. Educated at Wesley College, Sheffield, he entered the medical school of the old University College. He qualified L.S.A. 1901, taking the M.B.Lond. in 1913. He held all the resident posts in turn at the Infirmary, finally becoming house-surgeon, then the senior post. He started practice in Leeds, but in 1910 returned to Sheffield in partnership with the late Dr. C. W. Smith. He was a most careful and successful anaesthetist and at different times held posts as anaesthetist to the General Infirmary and Public Dispensary at Leeds, and in Sheffield to the infirmary, hospital, and Jessop Hospital. Always a loyal member of the B.M.A., he was honorary secretary from 1912 to 1915, and chairman of the Sheffield Division 1937-8. He leaves a widow and four children.

The writer of this note knew Birks first as a senior student, an influence for good in a school which was passing through a very difficult period. Later, as a resident, Birks acted as an unofficial tutor and mentor, and finally as a senior colleague. Invariably courteous and kind and helpful, he set an example to all of conscientious adhesion to duty. Later he became an ideal family doctor, equipped with hospital experience in all branches of medicine, supplemented by a high sense of duty and never-ceasing industry. He gave his patients not only good treatment but wise counsel on all kinds of problems. Perhaps the predominant impression left on one's mind was staunch loyalty to friends. After an over-strenuous life and looking forward to retirement, he was working at full capacity till a few days before his death. Men like Birks form the backbone of the profession, and to such as he it owes what popularity it enjoys among the general masses of the population.

A. E. B.

Lieut.-Colonel E. D. Caddell died at Farnham on May 27, aged 60. He was educated at King's School, Coventry, and Portora School, Enniskillin, and studied medicine at Trinity College, Dublin. Soon after graduating M.B., B.Ch. in 1906 he joined the R.A.M.C. and served in India, West Africa, Hong Kong, and Jamaica. In August, 1914, he went to France, and in the following year was awarded the Military Cross for a gallant act in saving a number of his patients when a hospital of which he was in charge was heavily shelled. After retiring from the R.A.M.C. he was for some time Secretary-General of the National Association for the Prevention of Tuberculosis. He rejoined the Army in August, 1939, to become S.M.O., Chatham. A correspondent writes: "Tommy," as he was named, was one of the finest scrum-halves of his day. He played for Trinity College, Dublin, for Ireland many times, and for the Barbarians and Blackheath. Those who knew him and played football with him will be deeply grieved to hear of his death; while many hundreds must still be alive who saw him play and will be sad to know that he has gone. His popularity was unbounded and everyone loved him. He was gay, brim-full of courage, and generous. No one could tell an Irish story better than he.

We regret to record the death of Dr. William Brand, formerly senior tuberculosis officer for Camberwell, and for three years chief medical commissioner to the National Association for the Prevention of Tuberculosis. He graduated M.B., C.M. of the University of Edinburgh in 1910 and early devoted himself to the study and treatment of cases of tuberculosis. At the Annual Meeting of the B.M.A. in Edinburgh in 1927 he was vice-president of the Section of Tuberculosis. Dr. Harley Williams writes: Popular health education was a neglected infant in 1927, when William Brand breathed new life into the propaganda work of the N.A.P.T. Horse caravans with leaflets and exhibits had previously toured England and Ireland, but Brand created something quite new. I well remember my first meeting with him one Sunday morning, when mysteriously he opened the door of a half-empty building where the present Tavistock House stands. William Brand was something of a Viking, with deep-blue eyes and an unhurried impressive manner, perhaps an atavism of his Shetland ancestry, and an artificial limb made his movements slow and deliberate. He began to speak about non-inflammable films, portable models, and travelling cinema projectors. After an hour or two's talk, he produced and solemnly laid out on the table a bottle of wine and a remarkable lunch, and we continued to discuss films and health exhibitions. He had spent months of patient work building up the best equipment and evolving most telling methods of display, and as the lecture tours developed and eventually covered England and Scotland his careful planning showed results. He had flashes of originality and dogged independence, and he was the most unselfish man I ever met. Never quick at forming judgments, he reasoned everything to the end, and always acted in a way that showed charity and concern for others.

The Services

Major-General G. A. Blake, late R.A.M.C., has been appointed Honorary Surgeon to the King, vice Major-General C. M. Finny, O.B.E., late R.A.M.C. (ret.).

Surg. Cmdr. D. C. Wilson, V.D., and Prob. Temp. Surg. Lieut. D. W. Wallace, R.N.V.R., have been mentioned in dispatches for gallant and distinguished service in the Middle East.

The King has approved the Mention of the following officers in recognition of gallant and distinguished services in the Middle East during the period July to Oct., 1941:

Royal Army Medical Corps: Acting Brigadier E. D. Pridie, C.M.G., D.S.O., O.B.E.; Brigadier (Local) C. W. Graham; Temp. Col. N. Cameron; Lieut.-Cols. R. McKinlay and L. S. C. Roche, M.C.; Majors (Temp. Lieut.-Cols.) C. E. W. Bower, D. Crellin, M.C., K. Fletcher-Barrett, C. A. Levy, A. R. Oram, M.C., G. W. Wigg, T.D., and D. C. Muir; Major N. Capstaff; Capts. (Temp. Majors) J. C. Dick, R. D. Forsyth, and J. D. W. McCracken; and Capts. P. W. Dill-Russell, A. Menzies, and T. St. J. H. Silvester.

Indian Medical Service: Major (Acting Lieut.-Col.) B. N. Hajra; Capt. and Brevet Major V. A. Edge; Capt. (Acting Major) G. B. Jackson; Capts. M. R. Chowdhury, K. S. Pillai, W. J. Young, M. Abbas, and S. Kapila.

Australian Military Forces: Col. J. K. Adey, O.B.E., E.D.; Lieut.-Cols. E. B. Jones, L. C. E. Lindon, T. A. Parry, and A. S. Walker; Majors R. V. Graham, I. M. Mackerras, J. S. Peters, and J. H. Stubbe; Capts. (Temp. Majors) R. G. Champion De Crespigny and R. H. Macdonald; Capts. W. H. Campbell, A. K. Green, and K. H. Heard.

East Africa Army Medical Corps: Lieut. (Temp. Capt. and Local Major) J. McC. Caldwell.

CASUALTIES IN THE MEDICAL SERVICES

Capt. William Elliott Young, R.A.M.C., was killed in action in Libya in May. He was born on September 6, 1910, and was the only son of Sir Alban Young, Bt., K.C.M.G. He was educated at Marlborough and Balliol, and after qualifying L.M.S.S.A. in 1937 took the degrees of B.M., B.Ch. of the University of Oxford. Soon after the outbreak of war he entered the R.A.M.C. as temp. lieut. and served in India before being posted to Libya. He leaves a widow.

Capt. Prabhas Chandra Banerjee, Army in India Reserve of Officers, who is recorded as died in an India Office Casualty List published on June 17, graduated M.B. of the University of Calcutta in 1932, and became a member of the B.M.A. in the same year.

War Subs. Capt. Shaikh Abdul Hakeem Qureshi, R.A.M.C., who is posted as died in an Army Council Casualty List published on June 27, was born on July 3, 1892, and received his professional education at St. George's Hospital, qualifying M.R.C.S., L.R.C.P. in 1924. He was in general practice in the London area until June, 1940, when he entered the R.A.M.C. as temp. lieut.

Missing.—Capt. H. M. S. G. Beadnell, R.A.M.C., Capt. G. M. Davies, R.A.M.C., Lieut. W. Donaldson, R.A.M.C., Major E. L. Ellis, R.A.M.C., Capt C. He[illegible]nt, R.A.M.C., Lieut. E. Leigh, R.A.M.C., Capt. D. Longbottom, R.A.M.C., Lieut.-Col. L. R. S. MacFarlane, R.A.M.C., Col. E. Percival, D.S.O., M.C., Capt. T. B. Smiley, R.A.M.C., Lieut.-Col. J. K. Steel, R.A.M.C., Brigadier C. H. Stringer, D.S.O., O.B.E., Lieut. H. B. Thomson, R.A.M.C.

Wounded.—Temp. Major E. E. Evans, R.A.M.C

Universities and Colleges

UNIVERSITY OF OXFORD

In a Congregation held on June 25 the following medical degrees were conferred:

D.M.—*O. H. J. Maxwell Telling.
B.M.—J. K. G. Webb, *M. Evnine.

* In absence.

UNIVERSITY OF CAMBRIDGE

The following candidates have been approved at the examination indicated:

FINAL M.B.—*Part II (Principles and Practice of Physic, Pathology, and Pharmacology)*: B. G. C. Ackner, W. B. Alexander, V. R. Arulanandom, W. E. S. Bain, G. P. Baker, R. C. Barclay, A. D. Barlow, G. M. Barrett, J. A. V. Bates, A. O. Bech, N. L. Birkett, J. A. Black, G. G. B. Blackman, P. F. Borrie, B. F. Brearley, M. M. Brown, R. J. K. Brown, P. H. Buxton, C. D. Calnan, T. O. Candler, F. S. Carter, W. E. Church, N. D. Compston, E. G. A. Crawshaw, N. F. Crofts, M. C. Cross, C. H. K. Daly, R. E. Danckwerts, P. M. Daniel, H. G. Danziger, R. W. Danziger, I. N. Darbyshire, J. Dean, G. H. Dhenin, R. Dobson, C. O. Edwards, R. M. Emrys-Roberts, W. F. Felton, J. H. L. Ferguson, G. E. Ffrench, J. L. Fluker, J. B. Foote, J. A. S. Forman, D. G. R. Fox, F. S. Glassow, E. C. E. Golden, N. J. Goorney, J. A. B. Gray, G. F. Green, E. J. Harrison, E. J. Holborow, R. A. Holden, P. Hughes-Jones, A. Hulme, W. P. U. Jackson, E. B. Jarrett, M. R. Jeffrey, D. M. Jeffreys, H. W. F. Jones, H. D. Juler, T. D. Kellock, D. E. R. Kelsey, J. M. S. Knott, H. P. Konig, H. M. Lawson, A. G. Leacock, T. L. T. Lewis, K. H. Lim, K. T. Lockhart, H. E. Lockhart-Mummery, A. Lyell, I. Macdonald, L. R. McLaren, S. J. R. Macoun, H. G. McQuade, R. G. Mathers, R. M. S. Matthews, L. H. H. May, R. H. Meara, R. B. Meyer, R. G. Miller, W. K. S. Moore, C. R. Naish, A. W. N. Oatway, R. A. Palmer, T. P. Pattinson, J. P. Paul, J. A. Peters, C. M. Phillips, J. S. Pippard, E. C. Poulton, J. R. K. Preedy, E. J. T. Prettejohn, P. M. M. Pritchard, S. H. Purser, J. F. P. Quinton, P. K. Renshaw, D. Rice, A. J. Rook, H. M. J. Rowan, J. H. B. M. Rowlands, J. G. Salter, D. L. Sandes, T. O. Scudamore, D. S. Short, E. G. Sita, J. F. P. Skrimshire, J. L. S. Smith, J. B. Stanton, J. C. Swanson, R. D. Sweet, H. D. Teare, J. R. Thompson, J. K. Wagstaff, R. J. Walker, J. C. Waterlow, R. B. Welbourn, J. C. N. Westwood, G. Wetherley-Mein, R. H. Wheeler, R. U. Whitney, J. J. Wild, D. I. Williams, H. I. Winner, J. F. R. Withycombe, J. B. Wyon. *Women:* A. Bolton, G. E. L. Cummins, P. Eskell, F. H. Lomax, V. U. Lutwyche, M. L. Macalister, H. C. Mason.

ROYAL COLLEGE OF SURGEONS OF ENGLAND

On July 2 three Fellows were elected into the Council to fill the vacancies caused by the retirement in rotation of Prof. E. W. Hey Groves, Prof. G. Grey Turner, and Sir Hugh Lett, Bt. The following Fellows were elected:

	Votes
HUGH WILLIAM BELL CAIRNS (Oxford)	502
GEORGE GREY TURNER (British Postgraduate Medical School)	495
Sir HUGH LETT (The London Hospital)	399

The following were the other candidates:

Lambert Charles Rogers (Cardiff)..	383
Philip Henry Mitchiner (St. Thomas's Hospital)	342
Sir Harold Gillies (St. Bartholomew's Hospital)	296
Lennox Ross Broster (Charing Cross Hospital)	212
Sir Lancelot Barrington-Ward (Great Ormond Street Hospital) ..	180
Charles Aubrey Pannett (St. Mary's Hospital)	143

In all 1,143 Fellows voted; in addition 17 votes were found to be invalid. Prof. Grey Turner, Sir Hugh Lett, and Prof. Cairns are all elected for the full period of eight years.

SOCIETY OF APOTHECARIES OF LONDON

At a meeting of the Court of Assistants held on June 23, with Sir Hugh Lett, Deputy Master, in the chair, Mr. Duncan C. L. Fitzwilliams was welcomed to a seat on the Court. A committee was formed to prepare evidence for submission to the Ministry of Health in connexion with post-war hospital policy and the organization of medical schools. Sir Stanley Woodwark and Dr. Geoffrey Bourne were reappointed adjudicators for the Gillson Scholarship in Pathology, and Sir Hugh Lett was re-elected as the Society's representative on the governing body of the British Postgraduate Medical School. Mr. L. Vernon Cargill and Dr. Arthur P. Gibbons were appointed to serve on the special committee of the Board of Registration of Medical Auxiliaries to discuss post-war planning, and Mr. Cargill to the Central Pharmaceutical War Committee. The Society's Gold Medal in Therapeutics was not awarded for 1942.

The following candidates have satisfied the examiners in the subjects indicated:

SURGERY.—P. L. McN. Armstrong, R. S. Gunewardena, L. D. Miller, W. C. Salter, P. R. Green, F. A. Rutland.

MEDICINE.—L. D. Miller, N. F. Murphy, C. J. O. Taylor, J. J. Wild, G. E. Barnard, M. M. El Badri, M. Fishman, H. G. King, E. E. Lieber, S. B. Nelles, Pak So, R. Powell.

MIDWIFERY.—G. R. S. Jackson, D. S. Jones, F. A. Rutland, R. M. B. Talbot, C. Fares, D. I. Fullerton, H. Gottschalk, W. H. Lillywhite, H. V. T. Payne, R. Powell.

The diploma of the Society was granted to L. D. Miller, N. F. Murphy, C. J. O. Taylor, J. J. Wild, G. E. Barnard, P. R. Green, M. M. El Badri, H. G. King, C. Fares, S. B. Nelles, M. Fishman, Pak So, and D. I. Fullerton.

Medical Notes in Parliament

Wartime Health

In a debate on the health of the nation, in the House of Commons on June 30, Mr. ERNEST BROWN said that all his reports showed that after 1,000 days of war the health of the nation was, in many respects, even better than it was in peacetime. The birth rate for 1941 was 14.2, compared with 15.1 in 1938 and 20.9 in 1916. For the first quarter of 1942 the rate was 15.5. This was the highest in any March quarter since 1931. The infant mortality rate for 1941 was 59, compared with 53 in 1938 and 91 in 1916. The rate for the first quarter of 1942 was 61, the lowest March quarter rate on record. The maternal mortality rate was 2.77, compared with 2.97 in 1936 and 4.12 in 1916. These figures showed that while over a long period of time the birth rate had been falling, over the same long period the survival rate had increased. The crude general death rate was 12.9 in 1941, compared with 11.6—the lowest on record—in 1938 and 14.4 in 1916.

Infectious Diseases: A Good Report

The risk of epidemic disease called for special care in wartime. Statistics showed that during the past 2¼ years of war the infectious disease rate had been normal, and on the whole, with certain exceptions, below the average. Apart from tuberculosis the only infectious disease which had risen during the war was cerebrospinal fever. In 1916 there were about 2,000 cases, and in 1938 and 1939 about 1,300 and 1,500 respectively. In 1940 nearly 13,000 cases were notified and in 1941 over 11,000. In the first half of this year there had been approximately 4,000 notified cases, compared with 7,000 in the first half of 1941. Although cerebrospinal fever was essentially a disease of wartime, a less marked but progressive increase had been taking place since 1935, and before the war it was thought that in any event a period of epidemic prevalence might possibly be approaching. It turned out that the fatality of the disease had been greatly reduced. In 1935 deaths rose to 69% of the cases notified, but during the last few years the mortality had fallen to 34% and 20%.

There were 50,000 cases of diphtheria in 1941, but the number of deaths had fallen from 5,300 in 1916 to 2,600 last year. During the last year or so the Ministry had been pressing a campaign for the immunization of children, both as a long-term policy and as a more immediate precaution against the risks of wartime conditions. Experience in other countries had shown conclusively the reduction in both the incidence of and mortality from this disease among an immunized child population. By the end of 1941 one-third of the child population under 15 in England and Wales had been immunized; but he was not yet satisfied. He was pressing the campaign, since experience justified the hope that if three-quarters of the children at each year of age below 15 could be made immune diphtheria might well-nigh disappear as a fatal children's disease.

Enteric fevers were natural sources of anxiety in wartime with the risk of disturbance of water supplies by air attack. We had done much to protect these supplies, and medical officers of health were prepared to offer inoculation against typhoid if circumstances called for it. There were in 1941 under 5,000 cases and 148 deaths, compared with 6,000 cases and 1,100 deaths in 1916. Not one of the deaths during the bombing was due to pollution by water-borne infection. Our comparative freedom from typhoid fever in a time of continuous bombing was something at which our American visitors marvelled.

In 1941 cases of pneumonia numbered 50,000 with 26,000 deaths (compared with 23,000 deaths in 1939 and 29,000 in 1940). New methods of treatment had been adopted, and, serious as this disease must remain, continued improvement was hoped for. The health services, preventive and curative, built up in the last two or three generations to cope with infectious diseases had stood up remarkably well to the conditions of war, but continued vigilance would be required. It was the desire of the Chief Medical Officer of the Ministry to get expert knowledge of how health could be maintained "put over" in language which ordinary people could make part of their common discussions. With regard to venereal diseases, steps were taken at the outset of war to expand the existing services and see that adequate supervision was available. Propaganda was being continued and developed along the lines thought most likely to be effective. It had always been on propaganda and education that we had relied, but work on limiting the spread of infection was hampered by lack of powers for dealing with those who were unwilling to submit themselves to examination and treatment, and who were known to infect numbers of others. While the increase in venereal diseases had not been so serious as might have been expected, its control must continue to receive close attention. Scabies had continued to increase during the war, and with the redistribution of population had become more widespread. It was really a household disease, and investigation of home conditions and the following up of contacts were essential measures in a campaign to limit the spread of infection. Powers taken by an Order under the Defence of the Realm Act, accompanied by improved methods of treatment, were facilitating the task of local health authorities. His impression was that the increase had been checked.

Referring to the problems of mental health, he said that institutional service had its own wartime difficulties. A number of institutions were surrendered at the beginning of the war to the needs of the E.M.S. with consequent overcrowding in others. In many of them, as in other hospitals, there had been and were serious problems of nursing and domestic staff, but there was a gratifying decline in the number of new cases requiring admission. At the beginning of the war it was feared that the strain of war conditions, particularly under aerial bombardment, would lead to a serious increase in mental disorders. The contrary had proved to be the case. In 1938 the number admitted was 30,000 and in 1939 the same; in 1940 it fell to 28,000 and in 1941 to 26,000.

Tuberculosis

In 1941 the number of deaths from tuberculosis was 28,669, compared with 28,144 in 1940 and with 26,176 in 1938. There was a jump in 1938-9, from which we had not recovered, but it had not gone further. In 1916 there were 53,858 deaths from tuberculosis. The black-out and overcrowding had made progress difficult. We needed to review our general approach and to give greater practical effect to the need for early diagnosis. In the past we had tended to concentrate on treatment rather than on early diagnosis, but the developments in miniature radiography during the last few months seemed to give a new and useful weapon as a means of detecting those cases in which more detailed examination should be undertaken. We now had the opportunity of getting British-made machines, and the fullest possible advantage should be taken of this development. He had ordered a number of sets of equipment through the Ministry of Supply both from America and from the makers in this country. When these could be secured he would make them available for use by local authorities as a part of their tuberculosis scheme. He was taking steps to see that trained teams were available for handling these machines, and he hoped that towards the end of the year we should be able to begin to use them on a carefully planned basis. In this way he hoped they would be able to detect and treat tuberculosis at an early stage, when they could, by a period of suitable treatment, restore a man or woman to health and self-sufficiency with the shortest possible interruption of normal life. Greater attention must also be given to the problems of after-care. This ought to be tackled on more comprehensive lines. No doubt both these points with others were engaging the attention of the committee of the Medical Research Council. To provide adequately for the treatment of tuberculosis there must be the necessary number of beds in both hospitals and sanatoria, and the necessary medical, nursing, and domestic staff for those beds.

Coming thus to the subject of nursing, Mr. Brown said that in 1939 there were 94,200 State-registered nurses, and 103,700 in April last. The Ministry's present difficulty in increasing accommodation for tuberculosis lay not in providing the beds but in finding nursing and domestic staff. They had sought to secure the necessary staff through propaganda, persuasion, and the good will of the professional organizations. The Minister of Labour was willing to direct women to service of all kinds in hospitals. There were many calls on the nursing profession in wartime, and over the whole field of the nation he could do with another 12,000 nurses. Nursing was a profession which, like that of medicine, had its special risks, and they were willingly faced. There was no ground, however, for the belief that nursing in sanatoria need involve any greater risk of contracting tuberculosis than nursing in other hospitals.

Medical Man-power

The amount of medical attention that the civil population could ask for must be less than in peacetime. The medical profession has had to meet very large calls for the Forces. The fact was that there was a shortage of doctors for the civil population, and the public must do what they could to get along with less medical attention. The Government could not ration doctors and limit everyone to, say, two visits a quarter, but everyone could make sure that no call was made on doctors that was not really necessary, and that when the doctor's services were required as full notice was given as possible, so that he could organize his daily rounds economically. He appealed to the public to recognize the difficulties of a grand and hard-worked profession, and do what they could to help them to carry out their essential duties. The medical, nursing, administrative, and technical staffs of local authorities had made, and continued to make, large contributions to the Services. We had been bound to recognize that this must be so, but at the same time there was a limit to the extent to which an increasing range of services could be discharged by a decreasing number of skilled staff. It would be the Government's object to concentrate on the effective maintenance of those essential services which were vital to the health of the nation.

Referring to post-war policy, he said that he had examined the interim report of the Medical Planning Commission, which had now been circulated to B.M.A. Branches throughout the country for discussion. Under Lord Rushcliffe the two committees on nurses and on midwives were making great progress. The Ministry were also preparing plans so that the moment the labour situation permitted and material was available they might resume their onward march in housing reform. The Ministry were playing an active part in connexion with post-war relief in Europe, which was being considered by an inter-allied committee on post-war requirements under the presidency of Sir Frederick Leith Ross. The technical aspects of medical relief and nutrition were to be examined by expert subcommittees. The Ministry were specially interested, and a good deal of preliminary work had already been done on the requirements of essential drugs in the immediate post-war period, and on plans for the campaign against epidemics, notably typhus and malaria, which became such a menace after the last war. In addition, diseases directly due to malnutrition were being studied.

Medical Views

In the subsequent debate Sir **FRANCIS FREMANTLE** said that the Medical Planning Commission's report was not a complete scheme; it should be regarded as a basis, and they should all study it carefully. With regard to the shortage of doctors, they must, in existing conditions, have regard to the needs of the Services. Up to last January no less than 20% of the general practitioners had been called up: that was one in five of the doctors, and those the healthiest, youngest, and keenest of general practitioners. Since then 1,400 more had been called up. It was a tremendous inroad into the profession and the health services. He commended the appeal which had been made to the public to help the doctors who were remaining in practice. The Priority Committee had gone ahead in recommending the concentration of practices. They might need the power to transfer doctors compulsorily from place to place. He hoped that that would not be necessary, and it should be done only in the last resort. He urged compulsory treatment for venereal disease.

Dr. **RUSSELL THOMAS** contended that the national health should be considered from the angle that good food was the basis of good health. The Minister should hesitate before he brought in some new system which might be disastrous to medical practice, with a resulting evil effect on the battle against disease. Dr. **EDITH SUMMERSKILL** urged that the Minister of Health should not consider discussing with the Minister of Labour the question of directing girls into tuberculosis sanatoria. The conditions and pay should be improved, and the girls allowed to know the danger. She was sure they would volunteer if the conditions were improved. During the war the increase in tuberculosis in young children had been very great, and the incidence of non-pulmonary tuberculosis, at least 40% of which was of bovine origin, should be carefully considered by the Minister. Mr. Brown ought also to make it compulsory for local authorities to teach their midwives to administer anaesthetics. There must be a big increase in diphtheria immunization. Dr. **MORGAN** urged the need for one unified national system of hospitals. He asked what national scheme the Minister had for the four essentials in a good tuberculosis scheme—early diagnosis, treatment, care, and prevention.

Miss **HORSBRUGH**, replying to the debate, said that both on the subject of health service for those between 14 and 18, and on that of dental treatment, the Ministry would examine what Sir William Beveridge reported on the insurance scheme and the whole of the social services. Of those in insurance societies where there was free dental treatment only 6% used it, and more education was wanted. There was a great shortage of dentists and dental mechanics. The Minister had no power to force local authorities to instruct midwives in the use of anaesthetics for mothers. The subject could be discussed, but then it must be left to the local authorities. They were awaiting the report on tuberculosis from the committee of the Medical Research Council, which would be examined as soon as possible. With good will it would be possible to launch a scheme by which people would be able to take up light work gradually after their treatment in sanatoria.

The debate was adjourned.

No. 24

INFECTIOUS DISEASES AND VITAL STATISTICS

We print below a summary of Infectious Diseases and Vital Statistics in the British Isles during the week ended June 20.

Figures of Principal Notifiable Diseases for the week and those for the corresponding week last year, for: (a) England and Wales (London included). (b) London (administrative county). (c) Scotland. (d) Eire. (e) Northern Ireland.

Figures of Births and Deaths, and of Deaths recorded under each infectious disease, are for: (a) The 126 great towns in England and Wales (including London), (b) London (administrative county). (c) The 16 principal towns in Scotland. (d) The 13 principal towns in Eire. (e) The 10 principal towns in Northern Ireland.

A dash — denotes no cases ; a blank space denotes disease not notifiable or no return available.

Disease	1942					1941 (Corresponding Week)

† Owing to evacuation schemes and other movements of population, birth and death rates for Northern Ireland are no longer available.

EPIDEMIOLOGICAL NOTES

Discussion of Table

In *England and Wales* the only large variations in the totals of notifications were for scarlet fever, with an increase of 292 over the preceding week ; and acute pneumonia and cerebrospinal fever, with decreases of 94 and 36 respectively. The largest rises in the incidence of scarlet fever occurred in Lancashire and Yorks West Riding.

The small increase of 39 in the notifications of whooping-cough was the result of the experience of Hertfordshire and Middlesex, where there were 81 and 20 cases more than in the preceding week. In the other counties the general tendency was for a slight fall in incidence.

Although the figure for measles was only 26 below that for last week, several counties showed considerable fluctuations. The largest decreases were those of Warwickshire 118, Yorks West Riding 113, Middlesex 97, Kent 80, Essex 74. The largest rises were those of Hertfordshire 121, and London 74.

Over half the notifications of dysentery were recorded in Lancashire and Yorks West Riding—16 in the former county from 7 administrative areas, and 23 from the latter (15 of them from the outbreak in Wortley R.D.).

In *Scotland* there was a slight rise in the incidence of measles and scarlet fever, 30 and 39 respectively more than in the preceding week. The largest rise in measles was that of Dundee, from 24 to 49 cases.

In *Northern Ireland* the epidemic of measles in Belfast continues, 350 cases—an increase of 8—being recorded during the week. The remaining 6 cases were notified in Lisburn.

Small-pox

An outbreak of small-pox has occurred in Glasgow. On May 29 a ship arrived in the Clyde from Bombay with a case of variola major, probably acquired at Capetown. All the 1,200 civilians and Service personnel aboard were vaccinated or revaccinated. Of the 12 known contacts, all except 2 were successfully vaccinated whilst incubating the disease, and the attacks were modified. In one case the vaccination was unsuccessful and the child developed small-pox in Swindon; 2 further cases have occurred among the population of Swindon. In Glasgow the disease has spread among the general population, and by the end of June there were 26 cases, 12 of which were from the ship's crew. Further cases, severe and modified, have been reported during the past few days and the disease has spread to the coastal town of Ardrossan. Up to the end of June, 3 patients—1 woman and 2 members of the crew—had died. Since then another death has been reported. The Department of Health for Scotland does not recommend that a national campaign for vaccination should at present be undertaken: so far some 300,000 vaccinations have been carried out in Glasgow.

Quarterly Return of the Registrar-General for England and Wales

The vital statistics for the first quarter of 1942 show a very satisfactory position. The largest birth rate for a first quarter since 1931 was recorded, being 15.5 per 1,000 ; in the March quarter of 1941 it was 14.4. The infant mortality rate was 61 per 1,000 live births, the lowest rate ever recorded in a first quarter and 15 below the average of the ten preceding first quarters. Stillbirths represented 3.5% of the total births registered, and, with the exception of 1941, when the rate was the same, was below the rate for recent years. The general death rate was 14.8 per 1,000, compared with 17.5 for the corresponding quarter of 1941, and 16.0 for the average of the five preceding first quarters. The births exceeded the deaths by 7,131 ; in the first quarters of the three preceding years the number of deaths was larger than the number of births by 850, 50,838, and 31,610.

Quarterly Return of the Registrar-General for Northern Ireland

A birth rate of 21.0 per 1,000 of the population was recorded during the March quarter of 1942, exceeding the average of the five preceding first quarters by 1.5. The infant mortality was 97 per 1,000 registered births, compared with 91 in 1941 and 100 for the five-year average 1937-41. There was a considerable reduction in the death rate, which was 16.1 per 1,000 of the population, or 3.2 below the value for the corresponding quarter of 1941, and 2.6 below the average rate for the first quarter of the five preceding years. The death rate of 1.08 per 1,000 for tuberculosis showed no change from the five-years average. Deaths from the principal epidemic diseases were below the average of the first quarters of 1937-41, with the exception of diphtheria, which caused 31 deaths compared with an average of 29.

Quarterly Return of the Registrar-General for Eire

The birth rate during the first quarter of 1942 was 19.2 per 1,000 of the population, an increase of 0.9 compared with the March quarter of 1941 and 0.3 above the average of the first quarters of 1937-41. An infant mortality rate of 80 per 1,000 registered births was recorded, compared with an average of 84 for the five preceding first quarters. The general death rate was 16.2 per 1,000, being 3.4 below the rate for the March quarter of 1941. The death rate from tuberculosis increased to 1.5 per 1,000. The numbers of deaths were 904 from pulmonary tuberculosis and 224 from other forms, compared with 765 and 207 for the average of the first quarters of 1937-41. Mortality from the principal epidemic diseases was below the average of the preceding five March quarters.

Returns for the Week Ending June 27

The notifications of infectious diseases in England and Wales during the week included: scarlet fever 1,320, whooping-cough 1,394, diphtheria 719, measles 6,375, acute pneumonia 655, cerebrospinal fever 108, acute poliomyelitis 12, dysentery 151, small-pox 2, paratyphoid 8, typhoid 6.

Medical News

The combined summer meeting of the Sections of Laryngology and Otology of the Royal Society of Medicine will be held at the Radcliffe Infirmary, Oxford, on Friday and Saturday, July 17 and 18.

A meeting of the Medico-Legal Society will be held at 26, Portland Place, W., on Thursday, July 16, immediately following the annual general meeting (which has been fixed for 5.15 p.m.), when Dr. G. Roche Lynch will deliver his presidential address on "Poisons and Poisoning." The president and Miss Roche Lynch will receive members and their guests at 4.15 p.m. and tea will be served.

A meeting of the executive committee of the Cancer Control Organization for Edinburgh and the South-East of Scotland was held in Edinburgh on June 23. One of the matters considered was the fuller use by doctors of the system of travel vouchers to enable their patients suffering or suspected to be suffering from malignant disease to attend at Edinburgh Royal Infirmary for treatment or for full examination. The honorary treasurer of the Organization is Prof. Annan, 22, Charlotte Square, Edinburgh, to whom subscriptions, donations, or bequests should be sent.

At the Central Criminal Court on June 30 Dr. Eustace Chesser and the Eclipse Press Services Ltd., trading as Rich and Cowan, publishers, were found not guilty of publishing an alleged obscene book and they were discharged. Both defendants pleaded "Not Guilty." Dr. Chesser in evidence said he wrote the book entitled *Love Without Fear* because he realized from his practice that physical ills were as nothing compared with mental troubles and difficulties. Fully 95% of the book consisted of quotations or restatements from previously published books. Three doctors who were called for the defence expressed the opinion that the book served a very useful purpose. The Common Serjeant, Mr. Cecil Whiteley, K.C., in his summing-up, said the defence had pointed out that people were much more open-minded now than they used to be, and that all the "hush-hush" about sex experience in Victorian times did a great amount of harm.

Representatives of the Empire Rheumatism Council and of the British Orthopaedic Association met in London last week to discuss means of co-operation in regard to the treatment of patients suffering from rheumatic disease. It was decided to appoint a Joint Standing Advisory Committee to achieve co-operation between the two constituent bodies; the committee to consist of Lord Horder (chairman); Mr. G. R. Girdlestone (vice-chairman); Dr. Hugh Burt (acting for Lieut.-Col. W. S. C. Copeman); Mr. Norman Capener; Mr. W. A. Cochrane; Squadron Leader W. D. Coltart; Prof. L. S. P. Davidson; Mr. A. G. Timbrell Fisher; Mr. S. L. Higgs; Brig.-Gen. F. D. Howitt; Prof. H. J. Seddon. The joint secretaries are Mr. Norman Capener and Sir Frank Fox.

A hospital pathological service, similar to that already functioning in the London Sectors, is to be provided for E.M.S. hospitals in the Provinces. Certain laboratories in each Region are to be recognized as area laboratories—that is, they will take work from other hospitals (to be specified by the Hospital Officer) as well as from their own, and will be staffed by whole-time pathologists. In addition "side laboratories," staffed only by technicians but supervised by a pathologist from the nearest area laboratory, are to be established as part of the upgrading of some E.M.S. hospitals.

The Department of Health for Scotland has now issued a booklet "Information Centres—A Handbock on their Organization" (price 6d.), which is a companion production to the recently published booklet, "Emergency Relief Organization, 1942," and, like it, is based on the experience of past air raids. The booklet shows how information centres should be organized and staffed, tells what sort of premises should be used and how they can best be adapted for their new purpose, and indicates the equipment required. Directors of information centres are told what their duties are, and staffs are given guidance on how to deal with the inquiries made to them.

Letters, Notes, and Answers

QUERIES AND ANSWERS

Duration of Anuria

Dr. Godfrey Lowe (Lincoln) writes: As a matter of interest, what is the longest period of anuria on record? A man of 75 has been laid up in bed for several months suffering from angina, sometimes of a very severe type; blood pressure averaging 160/100; very little albumin in urine. Suddenly he stops passing urine, no pain, no distension of the bladder. This goes on for eight days exactly. During this time he feels better than usual and the bowels act every other day or so. One morning he passes a small quantity of very pale green urine, and in a few hours the flow is normal, not excessive, and the colour becomes normal. There is a small amount of albumin present; the blood pressure is not raised any more; no oedema. He certainly had no drug to produce the green urine: a simple diuretic only was given. All this happened about three months ago. The patient is now very much better, sits up for meals, and even gets out in the garden; no stairs are allowed. I might add that he lives well out in the country and it was considered inadvisable to bring him into hospital for more thorough clinical investigation.

LETTERS, NOTES, ETC.

Herpes Zoster and Varicella

Dr. S. L. Brimblecombe (Stoke-under-Ham, Somerset) writes: Recently I have had two cases further suggesting a relation between these two diseases, and which also raise an interesting point. On May 2 I was asked to go to see a boy of 18 working on a farm, as he had a rash. I found him to be suffering with a severe attack of herpes zoster involving the right shoulder and upper arm. The people at the farm, who are milk producers, were much concerned to know whether it was infectious, and I told them that it was not. On May 20 I had a message to go to the same farm to see another boy of 12, as he had now developed a rash. On arriving there I was told rather reproachfully that, as I had said the first case was not infectious, the two boys had been allowed to sleep together in the same bed, with the result that the second boy now had a rash. Up till then I had not known of his existence as he is a recent evacuee. I found him with a well-developed chicken-pox. I was unable to get any evidence that he had been exposed to any other source of infection to this disease. The point arises whether in cases of herpes zoster one ought, while saying that the disease itself was not infectious, at the same time warn the occupants of the house that any of them who had not previously had chicken-pox may be liable to contract this disease as a result of contact with the patient.

Identical Twins in Different Environments

Dr. T. C. Scott Webb (London, S.E.18) writes: With reference to your annotation (May 23, p. 646) describing recent investigations into another case of identical twins, may I mention for the benefit of those who wish to read more on this subject the work by Prof. Lange, *Crime as Destiny*. A translation by Charlotte Haldane is published by Allen and Unwin at the modest price of 6s. I have not for many years read any book or article on any subject that has interested me so much as this. An excellent summary is given in *The Inequality of Man*, one of the Pelican series.

MEDICINE 100 YEARS AGO

Extract from the *Provincial Medical Journal* of July 9, 1842:

"The self-elected and irresponsible Council of the College of Surgeons, and a chosen few from the fellows of the College of Physicians, the representatives of the whole profession! Is our contemporary serious? By whom have they been chosen to represent the *whole* profession? What connexion has the College of Physicians with the body of the profession? Does any one to the east of Oxford-street—to say nothing of the rest of London, the seven miles round it, and the whole of England and Wales—regard the College of Physicians in any other light than as a corporation to which resort is had for the enjoyment of certain privileges? How many members of the College are scattered throughout the provinces? How many towns and counties are there in which a single representative of the College is not to be found—has ever been heard of? The pretension of the College to represent the profession is a pleasantry, nothing more. For the Council of the College of Surgeons it is unnecessary to say a single word, because the Council itself has pleaded 'guilty,' and we do not conceive that the gratuitous assertions of the Gazette can counterbalance the confessions of the criminal, or set aside the unanimous verdict of the public."

BRITISH MEDICAL JOURNAL

LONDON SATURDAY JULY 18 1942

THE DIAGNOSIS AND TREATMENT OF MALARIA IN ENGLAND

BY

WARRINGTON YORKE, M.D., F.R.C.P., F.R.S.

Professor of Tropical Medicine, University of Liverpool

One of the consequences of the war is the arrival in this country of a considerable number of cases of malaria, especially among members of His Majesty's Forces and the Mercantile Marine. As malaria is very amenable to treatment if recognized in time, and as it is highly dangerous and often fatal if not recognized and adequately treated, it is obvious that its diagnosis and treatment are matters of great importance. The object of this article, which has been written at the request of the War Office and Ministry of Health, is to set out briefly and simply the main points in the diagnosis and treatment of the disease.

Diagnosis

There are three common forms of malaria, caused by three different but closely related malaria parasites—viz., simple or benign tertian malaria, due to *Plasmodium vivax*; quartan malaria, due to *Plasmodium malariae*; and malignant or subtertian malaria, due to *Plasmodium falciparum*. These parasites inhabit the red blood cells. They have a regular cycle of multiplication, which in the case of simple tertian malaria is complete in 48 hours, in quartan malaria in 72 hours, and in malignant or subtertian malaria in about 36 hours. When multiplication is complete the young parasites escape from the infected red cells into the plasma and invade new red cells, and the patient experiences a malarial paroxysm.

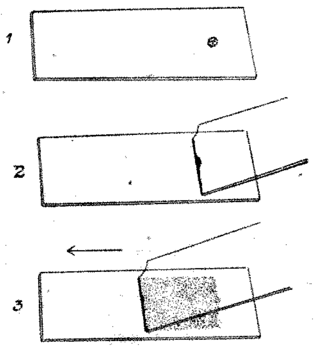

FIG. 1

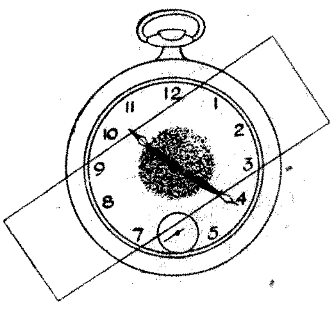

FIG. 2

FIG. 1.—Diagrams illustrating method of making thin film. 1. Place a small drop of blood near end of slide. 2. Apply spreader slide at an angle of about 30° and allow blood to flow across angle formed by the two slides. 3. Push spreader forward at uniform rate, drawing the blood after it; a thin evenly distributed film will result.

FIG. 2.—Diagram illustrating method of making thick film. Place a small drop of blood on centre of slide and spread with needle until it occupies about the area of a sixpence. N.B.—The film should not be so dense that the hands of a watch cannot be seen through it.

A definite diagnosis of malaria can be made only by microscopical examination of the blood and recognition of the parasite. While this may be beyond the scope of the general practitioner, it should at least be possible to make suitable blood films and send them to a pathological laboratory for a report. A method of preparing thin and thick blood films is shown in Figs. 1 and 2. Since the parasites disappear quickly from the blood as the result of treatment it is important that blood films should be made before any antimalarial drug is given.

Simple Tertian Malaria

Broadly speaking, acute malaria consists of a series of malarial paroxysms associated with progressive blood destruction, debility, and enlargement of the spleen. The paroxysms of simple tertian malaria are very characteristic. They consist of three stages:

Cold Stage or Rigor.—During this stage the patient complains of a sensation of intense cold, his teeth chatter, and he shivers violently; the feeling of cold is, however, entirely subjective, and if the temperature is taken it will be found to be raised. The cold stage lasts about an hour.

Hot Stage.—The feeling of cold gives place to a sensation of intense heat; the skin is hot and dry, the face flushed, the pulse full and bounding; headache and vomiting are often severe, and the temperature is raised to from 103° to 106° F. or even higher. This stage lasts 3 to 4 hours.

Sweating Stage.—The patient breaks out into a profuse perspiration, his temperature falls rapidly, the headache disappears, the vomiting ceases, and the paroxysm is over, leaving the patient somewhat exhausted but otherwise little the worse for his experience. This stage lasts 2 to 4 hours.

The duration of the complete simple tertian paroxysm varies, therefore, from about 6 to 10 hours. Typically in this type of malaria a paroxysm recurs with almost clocklike regularity every 48 hours, and the temperature chart can hardly be confounded with that of any other complaint (Fig. 3). Unfortunately, however, all the parasites in the blood of a case of simple tertian malaria may not complete the cycle of multiplication on the same day, some of them reaching maturity on Monday, Wednesday, Friday, and Sunday, and the remainder on Tuesday, Thursday, and Saturday. In such cases of so-called double infection there is a malarial paroxysm every day, and the temperature chart is of the quotidian instead of the tertian type (Fig. 4). But even here the chart exhibits certain striking characteristics—viz., the regularity of the daily febrile paroxysms, their short duration (6 to 10 hours), and the fact that the febrile disturbances are separated by a definite afebrile period lasting at least 12 hours. Except at the beginning of the attack before the paroxysms have become fully developed, when the temperature tends to be irregular, the simple tertian temperature chart is characteristic enough to suggest to the physician the true nature of the complaint.

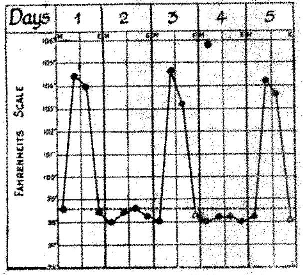

FIG. 3

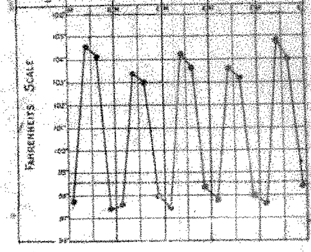

FIG. 4

FIG. 3.—Typical simple tertian temperature chart.
FIG. 4.—Quotidian simple tertian temperature chart.

If treatment is withheld and the disease is allowed to run its course, successive paroxysms result in progressive anaemia and debility; the spleen enlarges, the patient becomes icteric (haematogenous jaundice), and he often develops herpes, especially of the lips. If still untreated he may die of exhaustion, or the paroxysms may become less severe and finally cease and the disease become chronic. In this condition the patient remains in poor health; he is anaemic, the spleen is palpable, he often suffers from slight febrile disturbances, and is liable to relapse into the acute stage.

Quartan Malaria

Quartan malaria shows no essential differences from simple tertian malaria except that the cycle of multiplication of the parasite occupies 72 hours, and consequently the patient has a paroxysm, which is in all respects similar to that of the simple tertian paroxysm, every 72 hours—i.e., on the 1st, 4th, 7th, 10th days, and so on. Here again so-called double infections are not uncommon, so that not infrequently patients suffering from quartan malaria may have paroxysms on the 1st and 2nd, 4th and 5th, 7th and 8th days, and so on.

Malignant Tertian

Malignant tertian malaria is, however, a widely different and highly dangerous infection. The paroxysms are atypical; the cold stage is of short duration and ill defined or even absent, whilst the hot stage is greatly prolonged and is associated with intense headache, frequent vomiting, and severe constitutional disturbance. The ill-defined nature of the cold stage or rigor in malignant tertian malaria is a common cause of failure to suspect the true nature of the condition by medical men who have no special knowledge of the disease, and by the patients themselves, in whose mind the rigor is so firmly associated with malaria that a rigor and a malarial paroxysm have come to be synonymous.

The temperature chart of malignant tertian malaria bears little resemblance to that of simple tertian and is consequently a common cause of failure to diagnose the condition correctly. Owing to the prolongation of the hot stage the length of the febrile disturbance sometimes exceeds 24 hours. Moreover, as the interval between successive paroxysms is nearer 36 than 48 hours, the afebrile period between successive febrile disturbances is relatively short (Fig. 5). The greatest difficulty, however, is met with in cases of so-called double malignant tertian infection, in which the various paroxysms tend to run one into another, so that the temperature merely remits or is actually continuous (Fig. 6). It cannot be too strongly emphasized that a continuous temperature in malaria is a grave sign, and indicates that unless adequate treatment is promptly given the disease will soon end fatally.

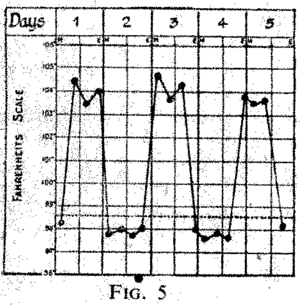

FIG. 5

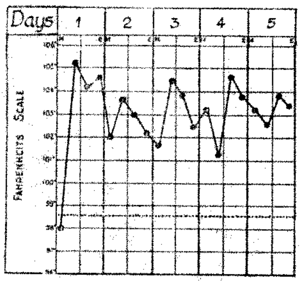

FIG. 6

FIG. 5.—Malignant tertian temperature chart.

FIG. 6.—Malignant tertian temperature chart, showing continuous fever.

In untreated acute malignant tertian malaria the general condition of the patient deteriorates much more rapidly than in the other forms of the disease. Persistent bilious vomiting (bilious remittent fever) is common, and the patient may quickly pass into a state of low muttering delirium (typhoid remittent fever).

The red corpuscles infected with the malignant tertian parasite show a marked tendency to stick to one another and to the endothelial lining of the capillaries, thereby occluding the lumen of the minute blood vessels. When this occurs, as is only too likely to be the case in untreated patients, there develop pernicious signs of the most diverse character depending on the site of the capillaries most damaged. Unfortunately, the brain capillaries are often involved, thus giving rise to the cerebral forms of the disease, one of the commonest manifestations of which is coma. The alimentary canal may be particularly involved, resulting in the gastric form of the disease associated with severe epigastric distress and incessant vomiting of blood-stained material, or in the dysenteric form associated with diarrhoea and the passage of blood. It is important to note that in these very severe forms of the disease the skin may be cold and the patient collapsed, although the rectal temperature is raised.

Rules for Guidance in Diagnosis

From the foregoing brief summary of the disease it is clear that clinical diagnosis, especially in the severest cases, is merely a matter of surmise in the absence of a blood examination. In these times, when so many cases are arriving at the main ports and are being distributed all over the country, it is imperative for the saving of life that medical practitioners should be on the look out for the disease and should know how to proceed. For their guidance the following rules are suggested.

1. Every sick individual recently returned from a malarial country should be suspected to be suffering from malaria, even in the absence of a history of previous attacks, unless some other diagnosis is obvious. This generalization applies even though the patient's temperature is normal at the time he is seen.
2. Ascertain whether the patient is obviously anaemic and whether the spleen is palpable; if these signs are present the suspicion that the case is one of malaria is strengthened, but their absence does not exclude malaria.
3. Make thin and thick blood films according to the directions given above and send them to a pathological laboratory for examination.
4. If the patient is ill, or if several days must elapse before the pathologist's report can be received, treat the patient on the assumption that he is suffering from malaria.
5. If the pathologist's report turns out to be negative, no harm has been done beyond the wastage of a certain amount of an antimalarial drug; whereas if it turns out to be positive the prompt treatment may well have prevented a catastrophe. In the event of a positive report the treatment of the acute attack must be followed by suppressive treatment as described below.

Treatment

There are two drugs which are invaluable in the treatment of malaria: (1) quinine, an alkaloid from cinchona bark; and (2) mepacrine, a synthetic compound. There is also another synthetic compound, pamaquin, which possesses certain special therapeutic properties, but, as it has no curative action on malignant tertian malaria and is highly toxic, it is unsuitable for general practice and need not be considered here. Unfortunately, although everybody of experience is agreed about the value of quinine and mepacrine, there is not a similar unanimity of opinion regarding the way in which they should be used. Little seems to be gained by discussing here the merits and demerits of the numerous courses of treatment that have been recommended, and it seems best to confine ourselves to methods which have been employed with uniform success for many years in the treatment of thousands of cases at the Liverpool School of Tropical Medicine.

Quinine

In the ordinary case quinine is best given in solution by the mouth. In Liverpool the following mixture, which is known as *mistura tropica*, is used:

℞	Quinin. sulph	gr. x
	Acid. sulph. dil.	♏xx
	Aq. chlorof.	ad ℥ss

A tablespoonful—i.e., 10 gr. of quinine—is given thrice daily for 4 days. If the patient is gravely ill, with persistent vomiting, oral treatment should be preceded by an intramuscular injection of quinine. The best salt for this purpose is quinine bihydrochloride, which is 50% soluble in water. Ampoules containing 10 gr. of quinine bihydrochloride in solution are supplied by the wholesale houses, and the contents of one of these ampoules should be injected into the muscle with aseptic precautions. Except in cases of cerebral malaria with coma, it is rarely necessary to give more than one injection, and treatment should be completed by the oral route as outlined above.

The outlook in cerebral cases with deep coma is notoriously grave, and in such cases an intravenous injection should also be given. The contents of the ampoule containing 10 gr. of quinine bihydrochloride should be diluted with 1/2 to 1 pint of hypertonic saline (3%) and run very slowly into the vein. If within 12 hours the patient has recovered consciousness and is able to swallow, the usual oral treatment should follow. If, however, he is still unconscious the intravenous injection should be repeated; but, as already stated, the outlook in such cases is bad—a fact which indicates the urgent necessity for diagnosis and treatment before this calamity develops.

In our experience, provided the patient is not comatose and moribund, this line of treatment invariably causes the parasites to disappear from the blood, the temperature to subside, and the general condition to improve enormously within 3 or 4 days; if this has not happened there is something wrong with the diagnosis, and some other cause for the illness must be sought.

Although this short course of quinine treatment cures the attack in a dramatic manner the infection is not sterilized, and if nothing more is done a relapse will occur within a few weeks in a large number of cases. With the object of preventing relapses and enabling the patient to return to work in safety, "suppressive" treatment must be administered. This consists in the oral administration of a small dose of quinine daily or of larger doses on each of two consecutive days each week. In Liverpool it is our custom to discharge the patient from hospital a few days after the treatment of his acute attack and to instruct him to take 20 gr. of quinine—i.e., one tablespoonful of *mistura tropica* twice daily—each Saturday and Sunday, for a period of 8 weeks. No other treatment is necessary, and the vast majority of patients are able to carry on their ordinary activities perfectly well and without further trouble. A few may have occasional slight relapses while taking this suppressive treatment, but these are not serious, and are dealt with by the subsequent week-end doses. Some cases, especially those of simple tertian and quartan malaria, relapse after the end of suppressive treatment, and in such cases treatment must be continued.

Mepacrine

This synthetic compound is supplied in tablets suitable for oral administration. The course for the treatment of the acute attack is 1 tablet (0.1 g.) thrice daily for 7 days. Its action is similar to that of quinine, and the 7-day course suffices to cause parasites to disappear from the blood and the signs and symptoms to subside. In the very severe cases referred to above, mepacrine treatment should be preceded by one or two intramuscular or intravenous injections of quinine bihydrochloride, as the salt of mepacrine suitable for injection may not be obtainable. With the object of preventing relapses, suppressive treatment must be administered in the form of 2 tablets (0.2 g.) of mepacrine each Saturday and Sunday for 8 weeks.

Conservation of Quinine.—In these days it is very desirable to conserve the limited stocks of quinine, and consequently whenever possible mepacrine should be used instead of quinine. Even if quinine is administered for treatment of the acute attack, mepacrine should be given for the subsequent suppressive measures, and the more so as there is some evidence to suggest that this drug is a more efficient suppressive than is quinine.

Toxic Effects of Quinine and Mepacrine

Apart from temporary tinnitus and deafness and sometimes slight gastric disturbance, there are no ill effects from quinine in the doses mentioned. Mepacrine is a dye, and even in the doses recommended may produce a yellow discoloration of the skin, which must not be mistaken for jaundice; the discoloration usually fades in the course of a week or two after the drug is stopped, but it may persist for as long as three months. A few patients suffer from mild gastro-intestinal effects, and very occasionally mepacrine acts as a cerebral excitant and produces mental disturbance and even mania, but these unpleasant effects are temporary, and soon disappear when the drug is stopped.

FACTORS INFLUENCING THE INCREASED INCIDENCE OF PULMONARY TUBERCULOSIS IN GLASGOW

STUART LAIDLAW, B.Sc., M.D., D.P.H., D.P.A.

AND

DUNCAN MACFARLANE, M.B., Ch.B., D.P.H.

(*From the Public Health Department, Glasgow*)

Following our previous investigation into the increased incidence of and mortality from tuberculosis in Glasgow (*Journal*, Sept. 27, 1941, p. 436), we have recently carried out a detailed investigation into the first 1,600 confirmed cases of pulmonary tuberculosis notified during the year 1941, with special reference to the effect of occupation and hours of work.

The Rise in Notifications

During 1941 the number of notifications of pulmonary tuberculosis again rose in Glasgow from the previous year's high level of 1,908 to 2,066. Table I compares the age and sex distribution of the cases notified during the two war years, 1940 and 1941, with the average of the last two peace years, 1938 and 1939.

TABLE I.—*Age and Sex Distribution*

Age	Males			Females		
	Average 1938–9	1940	1941	Average 1938–9	1940	1941
–15 years ..	118	92	134	84	111	136
–25 " ..	236	287	300	341	437	454
–35 " ..	165	218	214	181	214	219
–45 " ..	147	164	184	65	82	82
–65 " ..	222	206	230	65	53	69
65+ " ..	25	31	32	10	13	12
Total ..	913	998	1,094	746	910	972

The table demonstrates that the notifications of pulmonary tuberculosis in 1941 for males show an increase of 9.6% over 1940 and 19.8% over the average of 1938-9. The relative female figures are 6.8% and 30.3%. A feature of the table is that the under-15 age group has shown a marked increase in both sexes, and there has also been an increase in the over-45 age group confined to males. The number of cases recorded in the age groups 15–45 in males and 15–35 in females has only slightly increased during the past year, but exceeds 1938-9 by 27.3% for males and 28.9% for females.

Tables II and III give the total deaths from pulmonary tuberculosis, along with their distribution in age groups, for the years from 1938 to 1941.

TABLE II.—*Total Deaths*

	1938	1939	1940	1941
Males ..	534	537	664	615
Females ..	426	435	518	540
	960	972	1,182	1,155

TABLE III.—*Age Distribution*

Age	Males			Females		
	Average 1938–9	1940	1941	Average 1938–9	1940	1941
–15 years ..	25	25	34	27	26	30
–25 " ..	109	138	103	170	217	228
25+ " ..	401	501	478	233	275	282
Total ..	535	664	615	430	518	540

The figures show that the male death rate during 1941 is 13% above the average in 1938-9, although it has shown a slight fall since 1940; whereas the female death rate still continues to rise in all age groups, being just over 25% higher in 1941 than in 1938-9.

There is little change to be noted in the incidence and mortality of non-pulmonary tuberculosis, the notification rate being only 1.5% and the death rate 3% above 1940. Table IV shows at a glance the distribution of the non-pulmonary cases in the usual categories.

TABLE IV.—*Non-pulmonary Tuberculosis, 1939-41*

Year	Abdomen	Bones or Joints	Lymph Glands	Meninges	Skin, Genito-urinary, or Multiple	Total
1939 ..	82	166	90	137	52	527
1940 ..	80	198	130	184	60	652
1941 ..	108	226	104	182	44	664

Meningeal tuberculosis still remains relatively high, while bone and joint lesions again show an increase. A few more abdominal cases have been notified, but again the Senior Food Inspector reports no increase in the number of samples of Glasgow milk containing tubercle bacilli. In fact, only 18 out of 301 samples of transport milk examined during 1941 showed the presence of tubercle bacilli—that is, 6%, as contrasted with 6.3% for 1940 and 9.4% for 1939.

Occupational Analysis

Thus for another year the chief public health problem lies in the continued large number of cases of pulmonary tuberculosis. Table V compares the occupations among these pulmonary cases for the years 1938-41, and for simplicity of comparison gives the percentage increase for certain groups in 1941 compared with 1938-9.

TABLE V.—*Occupations in Notified Cases of Pulmonary Tuberculosis, 1938-41*

Group	Occupation	Average 1938–9	1940	1941	Percentage Increase
I	Scholars .	123	102	160	30
	Under school age	73 } 196	88 } 190	100 } 260	37 } 32·6
II	Domestic class ..	305	368	393	28·9
III	(*a*) Commercial class	248	212	230	
	(*b*) Professional class	21 } 269	28 } 240	46 } 276	2·6
IV	Soldiers, sailors, airmen	34	71	145	War increase
V	Miscellaneous (includes modellers, retired persons, no occupation)	97	91	74	–25
VI	(*a*) Tradesmen ..	187	230	204	
	(*b*) Skilled workers	219 } 406	338 } 568	294 } 498	22·7
	(*c*) Unskilled workers	210	231	254	
	(*d*) Labourers ..	142 } 352	149 } 380	166 } 420	19·3
	Total of (*a*), (*b*), (*c*), (*d*)	758	948	918	21·1
	Total of all groups	1,659	1,908	2,066	24·3

Although this classification is convenient for general statistical purposes, it does not detail the exact trades nor does it separate workers in heavy from workers in light industries. Therefore, in analysing the first 1,600 confirmed cases of pulmonary tuberculosis notified during 1941 we studied the classification of H. M. Vernon in his *Health in Relation to Occupation, 1939.* The advice of the officials of the Ministry of Labour was also sought, with the result that it was decided to rearrange Group VI of the above Occupation Table into three sections, namely:

Section A: Workers in heavy industries—general labourers, moulders, steel workers, riveters and platers, furnacemen and stokers, chemical workers;

Section B: Workers in medium-heavy industries—engineers and munition workers, machinists, turners, finishers, and fitters;

Section C: Workers in lighter industries—joiners and wood workers, paper workers, painters, workers engaged in the preparation of food, drink, and tobacco, textile and rubber workers;

and Group III (*a*) into two sections: (*x*) office workers, typists, clerks, draughtsmen, and telephonists; (*y*) shop employees, cleaners, and caretakers. Group II was subdivided into (*a*) housewives, and (*b*) domestic servants; while Groups I, IV, and V remain unchanged.

Each of the 1,600 patients investigated was carefully classified, and particulars were obtained of hours of work, overtime, A.R.P. or Home Guard duties, recreations, housing, contact infection, and time occupied in travelling to and from work. The travelling time varied a great deal, and could not satisfactorily be averaged. One remarkable feature was the large number who had to travel so far to work that they had to carry "pieces" (sandwiches) with them. This applied especially to workers in the heavy industries. The number who availed themselves of provided canteen facilities was found to be relatively small, the reasons given being that the catering in some of the canteens is monotonous and that the charges are often too high.

Of the 1,600 cases analysed, 470, or 28%, fell into Group VI (tradesmen, skilled workers, unskilled workers, and labourers), which was subdivided as above. Table VI illustrates the age and sex distribution of these cases according to the adopted subdivisions.

TABLE VI.—*Age and Sex Distribution of Group VI*

Section		Age Groups						
		–15	15–24	25–34	35–44	45–54	55+	Total
A	Heavy industries: Males ..	1	34	22	27	30	21	135
B	Medium-heavy industries:							
	Males ..	—	40	18	20	17	8	103
	Females .	1	64	10	1	—	—	76
C	Lighter industries:							
	Males .	—	24	6	15	4	6	55
	Females ..	1	88	8	1	3	—	101

Hours of Employment

From Table VI it appears that the young adults of both sexes are chiefly involved, and that with an increase of age the number of cases of pulmonary tuberculosis diminishes; but in the heavy industries there is a more even distribution of cases throughout the age groups. It was decided to subdivide the above sections into various working periods for comparative purposes. The results are shown in Table VII, in which are also included the working hours of clerical and shop employees, based upon statements made by the patients. The Labour Exchange has so far been unable to provide detailed figures of the number of persons employed in the different industries in Glasgow; it is unlikely that this information will be available for some considerable time. In any case, a really accurate estimate showing the interrelationship of occupation and pulmonary tuberculosis would demand a wider survey, as many persons who work in Glasgow live in the county areas, while considerable numbers of county workers live within the city.

TABLE VII.—*Distribution of Workers according to Hours of Employment*

	Average Number of Hours per Week				
	40–48	48–56	56–64	65–72	72+
Section A	%	%	%	%	%
Males	—	20	26	18	36
Section B					
Males	17	13	43	17	10
Females	14	46	31	9	—
Section C:					
Males	19	38	38	5	—
Females	35	45	14	6	—
Clerical Workers					
Males	29	32	39	—	—
Females	78	15	7	—	—
Shop Employees					
Males	48	24	18	10	—
Females	56	24	14	6	—

The first noticeable fact shown by Table VII is the percentage of those working longer hours among the industrial sections. In fact, 36% of those employed in the heavy industries were working over 72 hours a week, which could not possibly be conducive to good health, combined as it so often was with long periods of travelling and carried meals. It is noteworthy that four-fifths of the women employed in clerical work did not exceed a 48-hour week, contrasted with the low figure of 14% for machinists and munition workers. It will be seen that the advice given in the 25th Report from the Select Committee on National Expenditure (Session 1940-1) has been largely ignored. In that report (page 4) hours of work are dealt with and recommendations made. Paragraph V reads as follows: "The investigations already carried out by the Board indicate that over an extended period weekly hours of work should not exceed 60 for men and 55 for women." Applying these standards to Table VII, the percentage of workers in each group exceeding these figures can be tabulated as follows:

	Males	Females
Section A	67	—
Section B	48	40
Section C	24	20
Clerical workers	19	7
Shop employees	19	20

The subdivision of the commercial class, Group III (*a*), showed that 60% could be grouped under Section (*y*) (shop employees, etc.) and 40% under Section (*x*) (office workers, etc.). The conditions of employment and the risk of developing pulmonary tuberculosis in these two sections appear to be very similar. The proportion who were able to return home for their meals showed no appreciable difference, nor was there any distinction between the average housing and sleeping accommodation. The subdivision of the domestic class provided the following information: that 85% of the recorded cases were those of housewives and 15% domestic servants; that the illness of 10% of the married women showed a definite time-relation to pregnancy; and that 55 (20%) of the 270 cases recorded in the group were contacts with tuberculosis in the home.

Scholars and Pre-school Children

It is difficult to ascertain to what extent the number of pre-school children and scholars in Glasgow has diminished owing to evacuation during the year under review; but the number has certainly not increased, yet the number of children affected by tuberculosis has risen by over 32%. Our investigations showed that of the notified cases 24% had been contacts with open tuberculosis within the past five years, as against 18% in 1940 and 14% in 1939. Definite contact history was found in 66 of the 258 pre-school children and scholars notified, and it is possible this increase has arisen from the necessity for keeping chronic cases of phthisis at home owing to shortage of hospital beds. It is significant that, although the number of cases of pulmonary tuberculosis in this group has increased by 32% since 1938-9, there is an increase of 90% in the cases showing definite contact with previous open tuberculosis within the past five years.

Summary and Conclusions

Our previous study of tuberculosis in Glasgow dealt with the increased incidence of the disease from the outbreak of war up to the end of 1940. It was found that the main increase involved the age groups 15–45 in males and 15–35 in females, the rise being attributed to war conditions, such as long hours, overwork, strain, and curtailed rest.

The present study carries these observations further. It compares the returns for 1941 with those of 1940 and 1938-9. It also includes the results of a detailed investigation into the occupations and working hours of the first 1,600 confirmed cases of pulmonary tuberculosis notified during the year.

The number of notified cases of pulmonary tuberculosis in Glasgow among the young adult cases of both sexes still remains high, but the rate of increase during 1941 has slowed down considerably. On the other hand, the under-15 age groups of both sexes have revealed a very real increase, as has the over-45 age group in males.

The increase among young people of both sexes under 15 years of age is partly accounted for by an increased proportion of home contacts.

Our contention that overwork and long hours are playing a major part in the increased number of recorded cases since the war is supported by the facts embodied in Tables VI and VII, one of the outstanding features of which is that little increase has occurred among the commercial and professional classes, whose hours of work alone remain within reasonable limits. It will be observed that, whereas less than 20% of the commercial class exceed the recommended maximum hours of work, 67% of the workers in heavy industries and well over 40% in the medium-heavy industries are working in excess of these standards.

The increase in the domestic class may be accounted for by war strain and the fatigue caused by standing in food queues in all weathers. Inquiry shows that nearly 40% of the housewives notified during 1941 were employed in part-time war work in addition to their household duties. This is a new feature, entirely associated with war conditions, which, in our opinion, may account for the increased number of cases in this group.

ACTION OF PHOLEDRINE AND NEOSYNEPHRIN IN RAISING THE BLOOD PRESSURE

BY

P. C. ELMES

AND

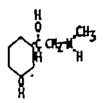
A. A. JEFFERSON

(*From the Department of Pharmacology, Oxford*)

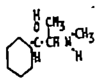
The use of substances having an action like that of ephedrine for raising the blood pressure still remains limited. Although ephedrine is sometimes injected when a spinal anaesthetic is employed, patients in collapse are ordinarily treated with nikethamide (coramine) or leptazol (cardiazol). Both are medullary stimulants and have no direct action on the heart. There is evidence that in animals they partly restore the blood pressure after previous depression with barbiturate. The effects are, however, seldom definite, and the doses necessary are very large indeed, being almost as great for a cat as the full therapeutic dose recommended for a man. The ability to improve the circulation is presumably due to stimulation of the vasomotor centre, causing vasoconstriction, some rise in blood pressure, and in consequence improved coronary flow.

If the chief effect desired is a rise in blood pressure, a substance which acts *directly* on the heart and blood vessels is clearly preferable. The more widely known agents which act in this way are ephedrine and pholedrine. Two other examples of such compounds on the market are neosynephrin (metasympatol) and phedracin.

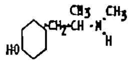
The formulae of these substances are as follows:



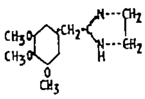
Neosynephrin (meta-sympatol)



Ephedrine



Pholedrine (veritol)



Phedracin

The properties of ephedrine are well known. Neosynephrin is practically unknown in this country, although it has been employed in America by a number of clinical workers, who find it greatly superior to ephedrine (Bittrich, 1939; Brunner and de Takats, 1939; Johnson, 1937; Lorhan and Oliverio, 1938; Lorhan and Lalich, 1940). In 1938 Jones and Wilson reported on the action of phedracin. They suggested at the time that it might be of use in spinal anaesthesia. Pholedrine (veritol), which was introduced in Germany by Rein (1937a, 1937b), has received only slight attention from clinicians in Great Britain. The many German publications on the clinical use of this compound are in general very favourable, and in this country Dodd (Dodd and Merton, 1939; Dodd, 1942) has recently published the results of its successful clinical use. He recommends that pholedrine, like all other pressor agents, should be used with circumspection and only when absolutely necessary. He employs 4 to 5 mg. intravenously and reports no untoward effects with this dose. Schoenewald, Schweitzer, and Steel (1940) found that in cats large doses (10 mg.) caused cardiac disturbances; small doses (0.2 mg.) had variable effects when the blood pressure was normal.

Experimental Investigation

We have compared these four sympathomimetic compounds, under standard conditions in animals with a depressed blood pressure, with the following results:

1. *Effect on the Blood Pressure.*—For each substance a series of five cats was employed; the animals received intravenous chloralose (0.08 g./kg.). The blood pressure was recorded from the carotid artery and enough nembutal was given to depress it to about 55 mm. Hg. Artificial respiration was applied throughout and the injections of the pressor agents were made intravenously at approximately hourly intervals. Doses which had previously been found to cause equal rises in blood pressure were used. They were: ephedrine hydrochloride 1.01 mg./kg., pholedrine sulphate 0.29 mg./kg., laevo-neosynephrin hydrochloride 0.05 mg./kg., and phedracin hydrochloride 0.79 mg./kg. Under these conditions the blood-pressure responses of the five cats could be expressed as averages in each series; the results are shown in Figs. 1 to 3. Ephedrine and pholedrine caused the most prolonged rise in blood pressure (Fig. 2), the response to the first dose of each substance lasting for about 45 minutes. Phedracin was briefer in its action (25 minutes), the effect of neosynephrin being the shortest of all (15 minutes). In such a preparation the response to an equivalent rise in blood pressure due to adrenaline does not last longer than about 4 minutes.

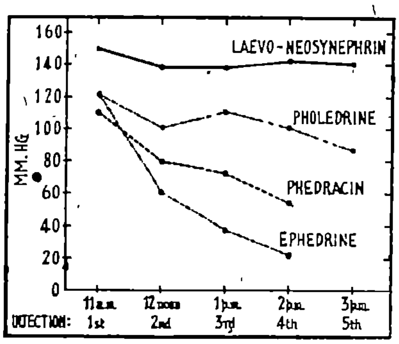


FIG. 1.—Showing the maximum height of the rise in blood pressure produced by successive injections of the four compounds given at hourly intervals. (Ordinate: mm. Hg above the initial level. Abscissa: Time.)

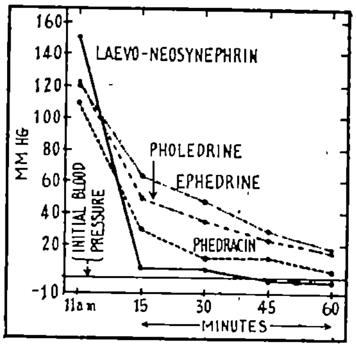

FIG. 2.—Showing the rate at which the blood pressure returns to its initial level after the peak of the first response. (Ordinate: mm. Hg above the initial level. Abscissa: Time.)

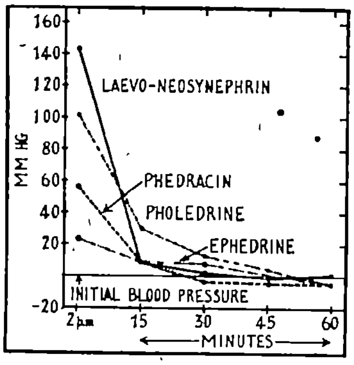

FIG. 3.—Showing the effect on the blood pressure of the fourth injection. Note the severe loss of activity of ephedrine and phedracin when comparing the peak of the response with that of the first injection, shown in Fig. 2. (Ordinate: mm Hg above the initial level. Abscissa: Time.)

Although the result of the first dose of ephedrine was satisfactory, we were never able to see an equivalent effect again in the same preparation, for invariably both the height and the duration of the blood-pressure response to subsequent doses were rapidly and progressively diminished (Figs. 1 and 3). We noticed exactly the same process upon injecting phedracin. However, the response to pholedrine over the first four injections showed little change, and the response to neosynephrin remained constant throughout.

2. *Action on the Heart and Blood Vessels.*—We also compared the action of equipressor doses of these substances on perfused vessel preparations (the rabbit's ear and the dog's hind limb) and on the isolated cat heart perfused through its coronary vessels (Langendorff method). We obtained the following results:

(i) Ephedrine and pholedrine act predominantly on the heart, whereas phedracin acts upon the vessels and neosynephrin upon both the heart and the vessels.

(ii) Ephedrine and pholedrine cause an increase in heart rate (55% and 45% respectively); neosynephrin does not.

(iii) In the experiments on the isolated vessels a regular vasoconstriction was produced by neosynephrin and phedracin. An effect was not always to be seen with ephedrine and pholedrine; a relatively higher dose was required to produce it, and the effect, when it did occur, was prolonged.

These last results are of use in determining the possibility of substituting these substances for adrenaline in local anaesthesia. We investigated the subject by injecting mixtures of procaine and these four compounds into the flank of young guinea-pigs—anaesthesia being tested by the absence of skin reflexes to pin-prick. In the short series which we carried out we did not find ephedrine, pholedrine, or phedracin to be of value. On the other hand, anaesthesia could be prolonged with neosynephrin to within 25% of the duration resulting with adrenaline. These results substantiate the suggestions of others (Tainter and Stockton, 1933; Henderson, 1940) that neosynephrin might find use in local anaesthesia, for it possesses the advantages of being a substance which remains stable in solution and which may be sterilized by heat.

Discussion

The therapeutic usage of a pressor substance depends in theory upon several factors, among which the following may be considered: (1) the mechanism of the pressor response—namely, whether it is produced by action upon the heart or upon the vessels; (2) the effectiveness of repeated doses; (3) the duration of the pressor response; (4) the existence of any unpleasant side-reactions.

Ephedrine acts mainly upon the heart, but its stimulant action is so violent as to render it potentially dangerous in all conditions in which the heart is not entirely healthy. In animal experiments it soon loses its activity when injected repeatedly, and a reduction occurs in the duration as well as in the height of the pressor response. The routine administration of ephedrine before the injection of a spinal anaesthetic has clearly little to recommend it, especially as an attempted increase in blood pressure above the normal is often the cause of cardiac arrhythmia. The administration of ephedrine very frequently inflicts great subjective discomfort on the patient, and upon these grounds too its use should be carefully controlled.

Pholedrine also exerts its pressor effects through powerful cardiac stimulation, though compared with ephedrine it is less often responsible for irregularities of the heart-beat. When given repeatedly it loses its activity far less rapidly than does ephedrine. The side-effects resulting from its injection into human beings in reasonable doses (4 to 5 mg. i.v.—maximum of 20 mg. i.m.) are slight.

Neosynephrin acts upon both heart and vessels in an extremely favourable ratio. It improves the filling of the heart, it adds to the strength of the beat, and while increasing the heart output often causes slight bradycardia. Though it shows a relatively brief action after intravenous injection into an animal, yet when given intramuscularly, as it very frequently is under clinical conditions, its length of action (30 to 40 minutes) is not greatly different from that of ephedrine or pholedrine (40 to 60 minutes) by the same route. It may be injected repeatedly with no loss of activity. After the administration of neosynephrin the patient rarely complains of even slight discomfort.

Phedracin appears to act almost entirely upon the vessels. It loses its pressor action upon repetition and, like ephedrine, its length of action is reduced. Owing to severe constriction of the skin vessels it may produce an unpleasant feeling of tightness.

Summary

The importance of using a substance which acts directly upon the cardiovascular system, when it is desired to restore a low blood pressure, is stressed.

Pholedrine, neosynephrin, and phedracin are compared with ephedrine in a series of animal experiments.

It is suggested that neosynephrin as well as pholedrine should be adopted clinically as a substitute for ephedrine.

The results obtained with phedracin do not favour its possible therapeutic use, although it might with advantage be given a further clinical trial.

Neosynephrin may be of value as an alternative to adrenaline in local anaesthetic preparations.

We wish to express our indebtedness to Prof. J. H. Burn for his constant help and encouragement.

A DEPRESSION-HYPOSEXUAL-ALOPECIA SYNDROME

BY

CLIFFORD ALLEN, M.D., M.R.C.P., D.P.M.
Squadron Leader, R.A.F.V.R.

AND

CARLYLE CARLYLE-GALL, M.R.C.S., L.R.C.P., D.P.M.
Squadron Leader, R.A.F.O.

Some years ago one of us (C. A.) treated a case of complete alopecia in a man of middle age. This man complained of deep depression, with very marked hypochondriacal trends, accompanied by absolute loss of sexual interest. The alopecia was complete and all hair-bearing areas were denuded, so that it was impossible to find any remaining hair. The lack of sexual interest occurred synchronously with the fall of hair, and the patient not only was impotent but showed no interest in his wife or other women.* Nor had he developed any abnormal form of sexual interest. This case progressed in spite of treatment, and when last heard of the patient had entered a mental hospital, as his depression had become severe enough for him to contemplate suicide. (Unfortunately, owing to the exigencies of the war, his notes are not available to us, nor is it possible to follow up his case.)

Record of a Recent Case

The present case is that of a man aged 33. He came from a normal family. His father died at the age of 64 from a perforated gastric ulcer, and still retained his hair at that age. His mother is still alive, is healthy, and has normal hair. She suffers from occasional attacks of migraine, but has no other symptoms of illness. He has five brothers; one died from a gastric ulcer, and another was operated on for the same reason. (One might suspect from this, and the fact that the patient also has gastric symptoms, that the family is an anxious one and that emotional disturbances tend to cause malfunction of the intestinal tract.) He had five sisters, but one died from pneumonia and one was murdered by her husband. The patient himself has had little other than the usual children's illnesses, except that he has suffered from typical migraine ever since he can remember: his eyes "half black out," then he sees bright lights and zigzags, and finally develops a severe headache which ends with nausea and sometimes actual vomiting. After the attack his head feels sore, but there is a general sense of well-being.

The patient was called up in November, 1940, and joined the R.A.F. He felt well and passed Grade I. A week later he was vaccinated, and seems to have reacted allergically to this. The first night he felt very chilled and his arm was excessively painful. He was faint next day and noticed that both arms had swollen—the oedema reaching down to his hands. He reported sick; but his condition was evidently not considered serious, and his arm was merely re-dressed. Then he complained of a sore throat and feelings of general malaise. This lasted about 14 days and then gradually passed away, although he never felt as well as he had done before. At the beginning of January, 1941, the hairdresser drew attention to a small area on the vertex of the head where there was no hair, and about the same time he himself noticed that there was a diminution of his sexual interest. Eleven weeks after the vaccination he attempted intercourse, but although he had been sexually deprived for some time he had an excessively delayed orgasm—so much so that his wife commented on it. He did not feel depressed at that period. With the passage of time the baldness developed in a patchy way, mainly over the posterior of his scalp. It then spread to the sides, and over the frontal regions the hair grew more and more sparse. He became quite bald. His eyebrows disappeared and he noticed large bare areas on his face, starting on each side of the chin and slowly spreading all over the lower face to coalesce with glabrous areas on the opposite side. This became so pronounced that he had to shave only once weekly instead of twice, as was his custom. The hair on his chest dropped out and a large amount of the pubic hair disappeared also. (This was mainly over the "male" abdominal distribution.) The only area unchanged appears to have been the axillary hair, none of which seems to have been affected even at the worst period. Simultaneously with the appearance of the extensive alopecia he felt depressed. That this was not the result of brooding on his condition but was related to his general feeling of malaise is shown by the fact that he stated definitely: "I felt depressed because I felt ill."

By June, 1941, he had reached the climax of his condition: his hair was absent except in the axillae, he was extremely hypochondriacal, was depressed, and was devoid of all sexual feeling. At this time he had an attack of abdominal pain, which he described as heartburn, but for which no organic cause was discovered. His sleep was poor and he ate little. He was transferred to an R.A.F. hospital in August, 1941, and has slowly improved since then. He was allowed home on short leave at intervals during September, October, and November, 1941. He felt little sexual desire with his wife, and when he did attempt intercourse—he felt he should do so to "prove his manhood"—his orgasm was delayed. The depression was sufficient to make him weep frequently, and he was unable to concentrate on anything. He could not write letters, and eight holes at golf exhausted him. He became excessively worried over his condition and has remained anxious about it ever since.

The condition appears to have followed his vaccination, but psychological factors may be important also—these being the fact that he was in some financial difficulty when he was conscripted into the R.A.F. and while away from home his wife developed a trivial meatal boil; but he was given a wrong idea of her state, and seems to have thought she was in danger of her life. Curiously enough, during his illness he suffered less from migraine than usual, having only three attacks during the whole of his service in the R.A.F.

In February, 1942, this man was still suffering from considerable alopecia and depression, and, as it was considered that it might be another year before he recovered, he was invalided, since it was unlikely that he would be of much value to the Service during this period.

Laboratory Investigations.—The patient's urinary male-sterone excretion was found to be 10.6 mg. a day, which is within normal limits. It is felt that this may not be significant either way, since he is now definitely recovering. The Wassermann reaction was negative.

Discussion

It appears to us that this patient is suffering from a syndrome, and since similar cases exist it is possible that it has not been recorded owing partly to the rarity of such extensive alopecia and partly because such cases fall into the hands of dermatologists who are not particularly interested in the concomitant psychological symptoms. The syndrome we would suggest consists of (1) wide-spread or complete alopecia; (2) depression with strong hypochondriacal features; and (3) diminution or complete lack of sexual desire, together with (4) diminished or absent capacity to fulfil the sexual act.

Alopecia.—The alopecia itself presents several problems. Is it directly dependent on the nerve supply or is it an endocrine deficiency which causes the fall? The distribution of the bald patches is not markedly symmetrical, so the suggestion is that the cause is endocrine rather than nervous. Again, there is no pattern suggestive of nerve or root distribution. Moreover, the delay between the causal factor and the onset of the loss of hair suggests an endocrine rather than a nervous mechanism at work. If it is an endocrine matter, then it would seem that there must be two endocrines—one which causes the growth of ordinary hair and one which stimulates the growth of sexual hair. The work of Broster and his collaborators (1938) on adrenal virilism has thrown considerable light on the endocrine factor—the adrenal cortex—and its relation to sexual hair. It seems probable, although there is no proof, that both hormones originate in the adrenal and complete alopecia is due to absence or diminution of them. The actual cause of the glandular damage, whether psychogenic or toxic, must be purely speculative. There is considerable evidence for the toxic origin. The amount of reaction evoked by vaccination, the loss of the feeling of well-being, and the fact that it is well known that alopecia commonly follows acute specific fevers, particularly if pyrexial, all suggest a toxic factor at work. On the other hand, there is the fact that this patient was in financial straits and was very anxious regarding his wife's health before he became ill. There are several well-authenticated cases in which anxiety has caused a fall of hair. For example, Spiegler (1918) recorded a case of a soldier who lost all his hair following the explosion of a shell close by him. Similarly, Pusey (1928) noted the loss of hair ten days after an emotional shock. Stern (1922) has suggested that the fall of hair is the extremity of the process which usually appears as greying of the hair. He, too, recorded alopecia following psychic trauma—the excitement of a barrage. Hurst (1940) describes cases of sudden greying of the hair within a week of strong emotional strain due to war-time experiences, also of permanent erection of the hair on the scalp and body, but does not appear to have seen any cases of alopecia.

Loss of Sexual Feeling and Power.—This lowering of sexual feeling and ability to carry out the act is very suggestive of endocrine disease. The attempts made by our patient seem to have had their origin in a psychic effort rather than a fundamental desire. It is a great pity that we were not able to arrange for investigation of his urinary male-sterone excretion during this time. On the other hand, he did not respond very strongly to injections of testoviron, so possibly the basic factor is a polyglandular one.

Depression.—The depression is accompanied by a heightened self-interest, which shows itself in hypochondriacal symptoms. The patient complains continually of his sad plight. He constantly draws attention to his terrible appearance and his miserable feelings. There is no retardation, and in neither of the cases seen has there been any delusional construction or hallucinosis. It might be tempting to explain the patient's reaction as a real response to his condition. There is no doubt that he does look bizarre with no hair or eyebrows, and he has some reason to complain and feel miserable. We would point out firmly that this is very unlikely to be the basic cause of his symptoms. We have seen pilots, air-gunners, and others who have suffered severe burns so that their faces were scarred and disfigured, but these men did not moan or complain. On the contrary, they were inclined to joke about themselves and were usually cheerful, although much more disfigured and more permanently scarred.

Prognosis.—The prognosis usually given by dermatologists is a hopeful one. Nevertheless the hair may take a year or even two before it grows again. Presumably the other symptoms also disappear with the reappearance of the hair, but we have had no opportunity of confirming this. That the prognosis is not always favourable is shown by the first case we saw. On the other hand, these cases must usually have a favourable termination, since wide experience in a number of mental hospitals has not brought us in contact with any further cases.

Treatment.—It would seem logical to treat these cases by psychotherapy, and this has been advocated by Hingston (1939), who claims favourable results. She also states that small doses of thyroid (1/2 to 2 g.) appear to have influenced the result. It seems more probable that testosterone propionate would be of value, but we are unaware of any really extensive and convincing experiments with it.

Conclusions

This combination of depression, alopecia, and lowered sexuality at once suggests some relationship, although doubtless a distant one, with Simmonds's disease. This illness, which is a polyglandular syndrome, is characterized by emaciation, anorexia, asthenia, precocious ageing, and general depression of glandular activity. It is usually accompanied by atrophy of the genitalia, cessation of the menses and sterility in women, and impotence and loss of sexual interest in men. There is in most cases a fall of the hair—so that the pubic and axillary hair may be absent. If the case is an early one the hair is found to be brittle and sparse. It is of interest to notice that Cahane and Cahane (1935, 1936) have described cases of diencephalic origin and suggested that these are related to Simmonds's disease. We feel that it would be unwise, on such slight clinical grounds as we possess, to make any suggestion as to the causation of the syndrome which we have described, except to point out its similarity to some of the other characteristics of endocrine disease and to suggest that it seems also to be of endocrine origin, although the cause of the damage to the glands is yet to be determined.

We have to thank Dr. Jocelyn Patterson for investigation of the sterone content of the patient's urine.

The effect of acute loss of blood on normal persons has recently been investigated by R. V. Ebert, E. A. Stead, and J. G. Gibson (*Arch. intern. Med.*, 1941, **68**, 578). Between 760 and 1,220 c.cm. of blood was removed from each of 6 persons within 6 to 13 minutes; this was estimated to amount to from 15.5% to 19.7% of the total blood volume. Five out of six collapsed with weakness, nausea, blurred vision, sweating, and fall in blood pressure. Before the onset of collapse the pulse rate increased from 14 to 30 beats a minute, and at the height of the collapse the rate became slow (between 30 and 40 beats a minute). Restoration of the plasma volume began immediately after the bleeding and continued for the subsequent 72 hours, at the end of which it was approximately equal to the volume before bleeding. The authors observed that during the first two hours after venesection the increase of volume was contributed by a protein-poor fluid, so that there was decrease in the concentration of serum protein. After this, fluid and protein entered the blood stream simultaneously. At the end of 72 hours approximately one-quarter of the plasma protein was protein which had entered the blood stream after the bleeding. The proportions of the albumin and globulin fractions were unaltered. The authors conclude that loss of blood acted as a physiological stimulus to the production of normal protein.

THE INCIDENCE OF BREAST-FEEDING IN A SMALL MINING TOWN

BY

ENID L. HUGHES, M.B., B.S., M.Sc., D.C.H.

Assistant M.O. (part-time), Northumberland County Council

This is a study of the incidence and duration of breast-feeding in Newbiggin-on-Sea, a small town on the coast of Northumberland, with a population of just over 9,000. The data have been obtained by interrogation of the mothers attending the infant welfare clinic. Since its establishment the clinic has been characterized by an absence of "class feeling," which may well be found even in a town of this type; and the friendly relations existing among the health visitors, midwives, and doctors of the town have resulted in an attendance in 1940 of 95.7% of the babies born there in that year, and living for at least six months.

Views concerning the Incidence of Lactation

A particularly interesting paper giving her own experiences of lactation and its difficulties is that of Dr. Lucy Naish (1913). In this she states that "weaning at or shortly after birth is very common among the well-to-do classes, and there are signs that it is spreading gradually to the less well-to-do." Spence (1938) quotes recent studies on the incidence of breast-feeding in Edinburgh, Newcastle, and other places, and reports a definite decline. Some of the findings quoted in his paper are included here, with the results of the present investigation. Robinson (1939) has studied the incidence of breast-feeding in Liverpool, using welfare clinic records over the period 1918-37. She, unlike Spence, came to the conclusion that there was no real decline in breast-feeding, but that there was a shortening of the period of lactation. Blessing (1937) has investigated the incidence of breast-feeding in a suburban metropolitan area in the U.S.A., all his patients being delivered in hospital. Only 38% of mothers breast-fed entirely to 1 month; all disliked "mixed feeding." He attributes the poor result to a system of divided control, in which the obstetrician took no responsibility for the child's feeding.

Present Investigation

The babies here studied are those born in 1940 of Newbiggin parents and continuing to live there till at least 6 months old. (This excludes 5 babies who died before the age of 6 months, the evacuee babies born elsewhere, and 12 babies whose mothers came to Newbiggin for the birth and moved away shortly afterwards.) The babies thus defined number 112—apart from these, 5 babies did not attend the clinic. The total is a small one, and does not justify generalities; any interest in this work lies in the fact that it is on 112 out of 117 possible attenders—i.e., 95.7% of the baby population of 1940; it is not considered "representative" of anything except this town in this year.

The population is mostly concerned with mining. An analysis of the fathers' occupation is as follows: Mining, 65; H.M. Forces, 12; traders, 9; fishermen, 8; labourers, 8; schoolmasters, 3; bus-drivers, 3; unemployed, 2; policeman, 1; professional footballer, 1; not known (illegitimate), 1. In this first full year of war wages approximated among the mining community to £3 a week; there was no real poverty, and no shortage of food. The Government scheme for cheap milk came into operation in August, 1940.

Most of the deliveries were by midwives. The figures are as follows: Doctors' cases, 13 (11.6%); hospital or nursing home, 13 (11.6%); midwives' cases, 86 (76.8%). Naturally the greatest number of babies were first children; the numbers of children related to their position in the family were: first children, 45; second, 35; third, 15; fourth, 8; fifth to eleventh, 9.

Data were obtained of the age at which weaning occurred; if it was preceded by a period of partial breast-feeding this was noted. Note was also made of the position of the child in the family and of how many previous children had been breast-fed, this term being used here to indicate "fed wholly on the breast to at least 3 months." (This figure was adopted to fall into line with Winternitz, quoted by Robinson.) Those mothers who weaned very early were asked whether they knew of any reason for this, and an analysis of their replies is given further on.

Results

The numbers were considered not to justify a very detailed analysis. The duration of breast-feeding is summarized in Table I.

TABLE I.—*Duration of Breast-feeding (112 Babies)*

Time	Complete Breast-feeding	Partial Breast-feeding	Weaned
Up to 2 weeks	67%	2%	31%
1 month	55%	2%	43%
3 months	32%	10%	57%
6 "	19%	9%	72%

This shows a very high percentage of early weanings. Spence (1938) states that in Newcastle (using figures derived from Princess Mary Maternity Hospital and from a middle-class nursing home) "satisfactory breast-feeding in the neonatal period is maintained only by three-quarters of the mothers"; but the Newbiggin figure is even lower.

In Table II is given a summary of some of the figures quoted by Spence (1938), together with some from Robinson, for comparison with the present work.

TABLE II.—*Percentage of Babies Wholly Breast-fed—Recent Investigations*

	Finlay (Edinb.), quoted by Spence (1938). 3,000 Cases (Home Visits)	Brewis, quoted by Spence (1938) Newcastle Municipal Welfares (1,326 Cases)	Robinson Liverpool Welfare, 1937 (439 Cases)	This Work (112 Cases)
10th–14th day .	87%	—	—	—
At 2 weeks	—	—	86%	67%
At 3rd.mth. .	—	58%	48%	32%
3rd–6th mth. ...	55%	—	—	—
At 6th mth.	—	34·7%	29%	19%
After 6th mth.	38·5%	—	—	—

Reasons given for Weaning before 2 Weeks

The proportion weaned (31%) was so high that the reasons for weaning were studied in some detail. Five of these 35 children were never put to the breast, on account of the mothers' serious illness. Two babies were very small twins, and breast-feeding was not attempted. One baby was weaned at 3 days because of the mother's sore nipple (hospital case). Six babies were either never put to the breast or no serious attempt was made to establish breast-feeding and they were "taken off" the breast when 1 to 4 days old; the usual explanation given was that "there was no milk." In two cases "breast abscess" and in one case "engorged breast" was given as a reason; and two at least of these three babies were stated to be "sleepy" or lazy feeders. In one case the mother had "too much milk," and had experienced such pain and trouble with a previous child that she made no attempt to breast-feed. She was a poor type of mother mentally, and was nervy and worried. Her husband was in a mental hospital, soon to be discharged, and she was upset about this.

In the remaining 17 cases the reason given was either that the baby was not gaining (and most mothers are very averse to giving, or are not encouraged to give, complementary feeds) or that, with getting up and about, the milk failed. Usually these two reasons were combined.

Feeding of Previous Children

Of the 35 babies weaned within two weeks, 18 were first children. It is interesting to know how the other (experienced) mothers had succeeded with previous children. In all, these 17 mothers with more than one child had reared between them 28 previous children. Only 6 of these had been breast-fed to at least 3 months: 22 had failed before this. (Of the 6 successfully breast-fed, 5 belonged to one large family of 11 children, the youngest of which was one of the 1940 babies.) Of the 1940 babies breast-fed to 3 months or more, 11 were first children and 26 were children of experienced mothers. These mothers had reared between them 44 previous children:

36 had been breast-fed to 3 months, 4 had failed, and of 4 no information was obtained.

The numbers are of course far too small for conclusions to be drawn, but they certainly tend to support one's ordinary observation that where a mother has managed to nurse one child she is likely to do so again. Thus breast-feeding of the first baby becomes even more important, in giving the mother experience and confidence.

Complementary Feeding

This is usually regarded as a step to be avoided if at all possible, as predisposing to rapid weaning. I have wondered, however, whether instruction in it may not help an anxious mother over a period of temporary shortage of breast milk. The knowledge that she can do this while her own supply is being improved may be very helpful, as, otherwise, a hungry crying baby may make her despair of feeding and lead to her weaning it immediately. I have therefore examined the clinic records to discover what evidence they afford of the value of complementary feeding in prolonging the total time of breast-feeding. The figures below refer to babies starting complementary bottle-feeding before the age of 6 months. The supplement advised was usually, to begin with, about 1/2 to 1 oz. of dried milk mixture, to be given at the end of some or all breast feeds. Breast-feeding was prolonged for *only 2 weeks* or less in 7 cases. It was prolonged for more than 2 weeks in 24 cases, 8 of whom were first babies. These 24 cases are analysed in Table III.

Table III

Case	Started Complementing at	Finally off Breast	Time Complemented
1	1 week	3 months	2 months 3 weeks
2	1 ,,	1 ,,	3 ,,
3	2 weeks	2 ,,	1 ,, 2 ,,
4	2 ,,	5 ,,	3 ,, 2 ,,
5	3 ,,	6 ,,	5 ,, 1 ,,
6	1 month	10 ,,	9 ,,
7	1 ,,	6½ ,,	5 ,, 2 ,,
8	1 ,,	2 ,,	1 ,,
9	5 weeks	4 ,,	2 ,, 3 ,,
10	6 ,, (pyloric stenosis operation)	9 ,,	7 ,, 2 ,,
11	2 months	4 ,,	2 ,,
12	2 ,,	5 ,,	3 ,,
13	2½ ,,	10 ,,	7 ,, 2 ,,
14	3 ,,	4 ,,	1 ,,
15	3 ,,	5 ,,	2 ,,
16	3 ,,	4 ,,	1 ,,
17	3 ,,	7 ,,	4 ,,
18	3 ,,	4 ,,	1 ,,
19	3 ,,	10 ,,	7 ,,
20	3½ ,,	10 ,,	6 ,, 2 ,,
21	3 ,,	4 ,,	1 ,,
22	4 ,,	6 ,,	2 ,,
23	4 ,,	6 ,,	2 ,,
24	5 ,,	7 ,,	2 ,,

Thus 8 babies were 1 week to 1 month old when supplements were started, and breast-feeding was prolonged for periods of from 3 weeks to 9 months; 4 babies from 5 weeks to 2 months old were enabled to continue for periods of from 2 to 7 months; 8 babies from 2 to 3 months old continued for periods of from 1 to 7 months.

On the whole, therefore, the results are encouraging, as in many of these cases (particularly those which continued for several months) the feeding was very largely on the breast, in some instances being practically re-established, the mother supplementing only when she realized that her own supply was inadequate. I have looked for the baby who "prefers the bottle to the breast," but found him only when the breast-milk supply was very poor or the mother inexperienced or unwilling.

Discussion

It is interesting to compare the results obtained by Pooler (1930), working in North Derbyshire with a population also largely concerned with coal-mining. From a detailed analysis of 100 cases of early weaning he finds that in 63% the primary cause of weaning is the return to domestic duties. In about half of these there are additional predisposing conditions—e.g., too frequent feeding, depressed nipples, etc. Spence (1938) says: "Probably the most important cause of failure to breast-feed among those who desire to do so, is the temporary inhibition of lactation which occurs shortly after the lying-in period when the mother returns to her household duties."

Most of the Newbiggin mothers get up at the tenth day, and although the midwives continue to visit up to the fourteenth day many of the mothers have to plunge at once into full housework. Some of the fisherwomen, in addition, work at mending and setting the nets. It is too costly for many to arrange for extra help in the house after the two weeks; but, in any case, the importance of returning gradually to their normal duties is not sufficiently recognized by many mothers, one of whom, when urged to do so, said that "that would be behaving like an invalid."

Full details have been given of the 35 mothers who weaned in the first two weeks, as they formed nearly a third of the whole. For babies to be weaned at or before two weeks surely implies (except in the case of the mother's illness) either a very feeble will to nurse, or mismanagement, and sometimes results from the influence of friends and relatives, ignorance as to the value of small complementary feeds, or proper requirements of rest on getting up.

The midwife is often blamed for not seeing that breast-feeding is established; but, unlike the monthly nurse of the better-off classes, she is not in constant attendance on the mother. This ever-available support and advice is given by the grandmother or other female relative. (Sometimes the grandmother is anxious about some previous illness of her daughter's which she feels may recur with the strain of breast-feeding.) Most midwives are as keen as anyone to establish breast-feeding, but their one visit a day (after the third day) cannot replace the home atmosphere. Is enough care taken, one wonders, in educating the grandmother as well as the mother in the importance of breast-feeding, and of meeting the grandmother's doubts as to her daughter's fitness for this? The opinion of the senior midwife in the town was that many of the young mothers wanted to go to dances with their husbands, and so were not keen to establish breast-feeding.

Another point is that a young mother, especially with her first baby, becomes extremely anxious when it cries, and she is apt to attribute this to her own deficiency—"Not enough milk" or "Milk not doing any good"—an opinion that is often supported by her own mother. It is not easy to persuade her to persevere under these conditions, and, especially if the baby is not obviously gaining, she will turn with relief to a bottle and a box of food for which she feels she is not (psychologically) responsible.

Most of these mothers also firmly believe that it upsets the baby to complement, and that the two milks will not mix well at the same feed. Regurgitation of curdled milk is interpreted as a serious symptom: I have not met one mother who realized that "souring of the milk" was a natural and proper process. Education on this point might avoid many anxieties. It is probably this belief that leads often to the rapid weaning of a baby on complementary feeds; but the figures already given suggest that, with encouragement and advice, complementary feeding may be very valuable in prolonging lactation.

Summary

In a small mining town in Northumberland 31% of 112 babies born in 1940 were weaned before the age of 2 weeks; 57% were weaned by 3 months.

Reasons for early weaning are discussed. It is suggested that early return to domestic duties played an important part.

The anxieties both of the mother and of her home attendants need more attention and understanding in order to create a favourable environment for breast-feeding; this is specially important with the first child.

Complementary feeding has enabled lactation to be carried on for several months in some cases, and might be tried with more confidence in the neonatal period.

I am grateful to Dr. Tilley, acting medical officer of health, Northumberland, and to Dr. Jamieson, maternity and child welfare officer, Northumberland, for permission to publish these results. I also wish to thank Miss McDermott and Miss Weston, health visitors at Newbiggin, for their ready help and co-operation in the collection of the data.

Medical Memoranda

Morbid Anatomy of Chronic Otitis Media

It is interesting to try to envisage the morbid anatomy of the temporal bones from the clinical data, radiographs, and other diagnostic aids. The more obvious abnormalities may prove mere palimpsests in the light of what is found at operation. The following 3 unilateral cases were among those chosen for conservative operation by the transmeatal route, with a view to providing better drainage and access for treatment.

Case 1.—The patient, aged 25, had been sent home from Gibraltar owing to otitis of ten years' standing. A small polypus protruded through an oblique perforation. Radiographs showed that pneumatization on the left side had been arrested in infancy (Figs. 1 and 2). At operation in November, 1941, a large infected cavity in the region of the mastoid antrum was evacuated; the rest of the bone was compact. The meatus was narrowed by osteophytes. At the end of December healing was in an advanced stage.

Case 2.—A sergeant aged 42 had been sent home from Iceland with a view to surgical treatment. He had had a perforation in Shrapnell's membrane for 15 years. At operation in August, 1941, a well-pneumatized temporal bone was found to have been invaded by a small cholesteatoma resembling a chamois-leather pocket, with foul green contents (Fig. 3). Within 8 weeks the ear was dry and healed and the hearing had much improved.

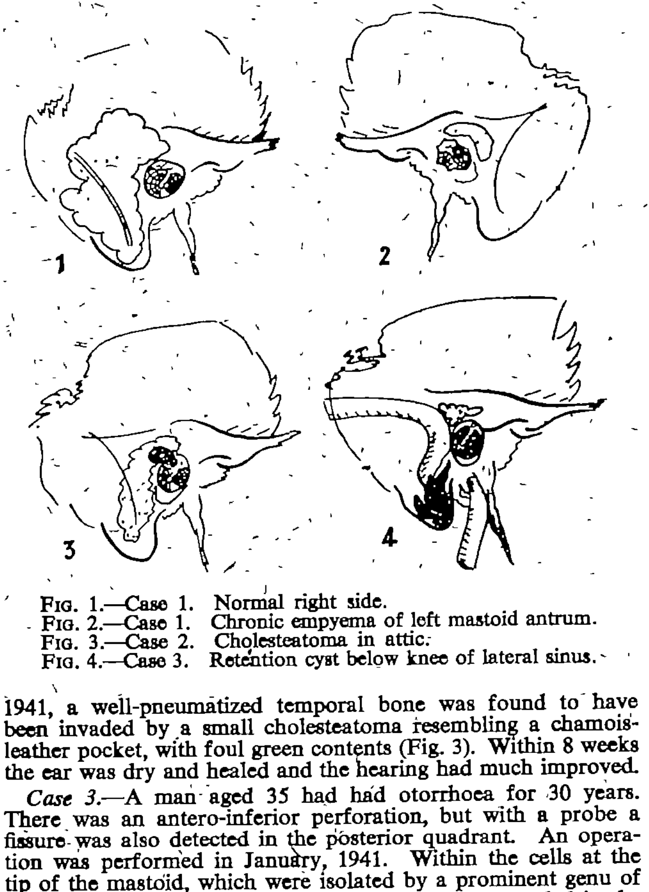

FIG. 1.—Case 1. Normal right side.
FIG. 2.—Case 1. Chronic empyema of left mastoid antrum.
FIG. 3.—Case 2. Cholesteatoma in attic.
FIG. 4.—Case 3. Retention cyst below knee of lateral sinus.

Case 3.—A man aged 35 had had otorrhoea for 30 years. There was an antero-inferior perforation, but with a probe a fissure was also detected in the posterior quadrant. An operation was performed in January, 1941. Within the cells at the tip of the mastoid, which were isolated by a prominent genu of the lateral sinus, was encysted fluid (Fig. 4). Suspended in the fluid were scintillating crystals (rectangular, with a corner missing) of cholesterin. The walls were of burnished bone, any lining membrane being invisible. The patient was subsequently passed A1 for the R.A.F. military police.

W. O. LODGE, F.R.C.S.Ed.,
Honorary Surgeon to the Ophthalmic and Aural Dept.,
Royal Halifax Infirmary

J. M. Brookhart, F. L. Dey, and S. W. Ranson (*Endocrinology*, 1941, **28**, 561) observe that there is direct evidence for believing that the site of the erogenic action of the gonadal hormones is in the central nervous system. In experimental work on guinea-pigs they found that animals with lesions in the anterior part of the hypothalamus fail to show pro-oestrual or oestrual behaviour, and that such behaviour cannot be induced in them by the injection of ovarian hormones alone or in combination with pituitary hormones.

Reviews

IMMUNOLOGY OF PARASITIC INFECTIONS

Immunity against Animal Parasites By James T. Culbertson, Assistant Professor of Bacteriology, College of Physicians and Surgeons, Columbia University. (Pp. 274. 36s. 6d.) New York: Columbia University Press; London: Oxford University Press.

Thirteen years have elapsed since the publication of Prof. Taliaferro's book entitled *The Immunology of Parasitic Infections.* The present volume of similar title may be regarded as a continuation of the first. In fact the author states in his introduction that he has taken Taliaferro's book as its point of departure, so much so that very few of the references quoted in the present volume antedate 1929. There is no doubt that Taliaferro's book, which collected in an authoritative manner a vast amount of scattered information on the subject of immunity to animal parasites, was followed by a great extension of researches in this field. It is chiefly with the results of these later investigations that the present volume deals.

The book is divided into three parts. Part I discusses natural resistance and acquired immunity and the general principles underlying these phenomena. Part II is devoted to the immunity to specific diseases, the most important of which is malaria. Part III considers applied immunity, the relation of immunological to morphological classification of parasites, and serological methods of diagnosis of infections.

Those who have followed the literature of the past ten or fifteen years will be well acquainted with the extent of that devoted to the immunological aspects of animal infections. Formerly the study of parasites was almost entirely morphological, but of late years these have given place very largely to immunological investigations, and it is with these that the author of this book deals so successfully that it is difficult to find fault with anything he has written. He has certainly given a most valuable review of the modern position of his subject, and immunologists and parasitologists alike will find Culbertson's *Immunity against Animal Parasites* an indispensable aid to their studies and future investigations.

ASPECTS OF GENETICS

New Paths in Genetics. By J. B. S. Haldane, F.R.S., Weldon Professor of Biometry in London University. (Pp. 206. 7s. 6d. net.) London: George Allen and Unwin. 1942

Books that comprise a series of special lectures can seldom possess, unless very extensively rewritten, the characteristics of textbooks or monographs. They have more the nature of a commentary, choosing for particular attention those aspects of the subject which have interested the author and to which he has devoted his own researches. Prof. J. B. S. Haldane's book is based on lectures delivered in Holland in March, 1940. The preface shows that he seems to feel that some apology is now needed for confining the published account to certain aspects of genetics, for a relative dearth of references, and for dealing so largely with the work of himself and his associates. It is clear that the lectures have been prepared for publication under conditions of considerable strain. He says that he hurried to get them into book form, but that meanwhile "I was called upon to undertake researches for the British Government designed to save the lives of certain members of its armed Forces. This research not only occupied most of my time, but left me in a state of fairly extreme physical exhaustion, for the conditions which I was investigating were of such a character as to cause loss of consciousness and other serious symptoms." He also states: "I do not even know whether I shall enjoy life and liberty long enough to correct the proofs." Actually, few if any readers will feel that any apology is necessary and all will enjoy these fascinating essays on selected topics in the spirit in which they were no doubt welcomed as lectures.

After a general survey a detailed analysis is given of certain biochemical researches, notably those concerning the development of colours in flowers. The next essay deals with genetics and development and is based on Gruneberg's interesting analyses of the manifold and complex effects of certain genes in the mouse. The remainder of this small volume, nearly half in fact, is devoted to human genetics. In this field recent contributions from this country have been substantial and important, and, if pride of place as regards basic theoretical advances must be awarded to the researches of R. A. Fisher, Haldane is easily first in ingenious and fruitful analyses of human data. A recent leading article in these columns[1] dealing with the sex chromosomes of man was largely concerned with his discoveries, and other contributions have formed the basis for several annotations.[2] Haldane in this volume discusses a number of these fascinating discoveries and speculations, and must be congratulated on his success in making some difficult topics comparatively simple to anyone with a knowledge of elementary genetics.

Minor criticism is not called for, but the remarkable statement on page 194 must surely be due to the compression into part of a single sentence of a doubtless complicated affair: "I have personally been fortunate in securing the advice, if not always the agreement, of his distinguished successor Prof. Fisher, until, as the result of a brutal assault by employees of University College, London, whilst attempting to enter his laboratory, he was compelled to leave London." Foreign readers will be numerous, and it is to be feared that some of them may form an exaggerated impression of the perils of English academic life.

DISEASES OF THE HEART

Diseases of the Heart, Described for Practitioners and Students By Sir Thomas Lewis, M.D., F.R.S., F.R.C.P. Third edition. (Pp. 297. 15s.) London: Macmillan and Co. 1942

Nine years have elapsed since the first publication of *Diseases of the Heart,* by Sir Thomas Lewis. During this period it has kept its place as one of the best, and perhaps the best, short treatises in English on heart disease. In this third edition the work is essentially in its original form, but a careful revision has been undertaken and such relevant advances in knowledge as might prove useful to practitioners have been incorporated. Cautiousness of statement, avoidance of theorizing and conjecture, and insistence on bedside as distinct from instrumental methods are still cardinal features of the work. While radiological and electrocardiographic methods are described in relation to their specific uses in particular maladies, no separate discussions of these methods have been undertaken. In the past decade the conception of left ventricular failure has developed and has undoubtedly contributed to a more complete understanding of heart failure; it is therefore rather surprising that this important principle has not here been more unreservedly recognized and more closely woven into the text. The chapter on effort syndrome is naturally of current interest; present-day problems of medical examination of recruits and conditions of military service which differ from those obtaining in the last war have reorientated ideas on this functional disturbance, and there can be no doubt that psychological rather than infective causes preponderate.

To the student, the practitioner, and indeed all who seek a lucid, logical, and practical exposition of cardiology, free from fads and fancies, this work by Sir Thomas Lewis cannot be too strongly recommended.

CALCULATION OF FOOD VALUES

Food Values in Shares and Weights. By Clara Mae Taylor, Ph.D., Assistant Professor of Nutrition, Teachers College, Columbia University. (Pp. 92. $1.50.) New York: The Macmillan Company. 1942

The appearance of Dr. Clara Taylor's name as the sole editor of this book, which is intended to replace Rose and Taylor's *Food Values of Recipes in Shares and Vitamin Units,* comes as a melancholy reminder that in the recent death of Mary Swartz Rose not America only but all the civilized and scientific world lost one of its leading nutritional experts. Dr. Taylor has dedicated this book to the memory of her late colleague, and this serves further to emphasize the fact that in first proposing the "share system" for assessing diets Prof. Rose added an ingenious and extremely useful device to the many pieces of scientific research that constituted her contribution to the theory and practice of nutritional science.

The idea seems simple enough once someone had the ingenuity to think of it. You take the average requirements of the "average" individual for each essential nutrient, and divide them all by thirty. Each "share" so calculated then becomes the unit for dietary evaluation and planning. Every food will, according to its composition and the size of the portion, contribute a certain number of "shares" of its individual nutrients. These may be tabulated for all the foods under consideration, the nutrient shares totalled, and the results compared with requirements—obviously 30 shares of each nutrient for the "average" individual, but different amounts for others, according to sex, age, occupation, and so on.

Dietary analyses thus constructed are free of all units: ounces, grammes, pints, millilitres, microgrammes, international units all disappear, and calculations are made in terms of "shares" only. To this end Dr. Taylor's book gives, first, recommended daily allowances (in shares) of specific nutrients for men, women (non-pregnant, pregnant, and lactating), and children of various ages. Then come 33 pages of a table showing the "share" analyses of all the most important American foods, both raw and as prepared according to certain selected recipes, of which some details are given. A corresponding table of food values in weights occupies another 30 pages. There is much additional useful information in this book, which is of excellent appearance and handy shape, as well as some "specimen blank" pages ruled for the reader to use on his own diets. Practitioners would certainly derive much interest from reading this book, and still more from using its procedure and facilities to examine the diets of their own households; sometimes, possibly, the interest might be tinged with a little disquiet.

Notes on Books

Basic Concepts in Social Case Work, by HERBERT H. APTEKAR, is published in this country at 15s. 6d. by the Oxford University Press. It is a book for teachers and students of social case work and deals with the fundamental approaches to the subject with numerous illustrative examples. This may not prove of great interest or importance to medical readers except in so far as they ought to know something of the principles on which the social services ancillary to medicine work. Two important principles are insisted upon in this book which perhaps all social workers would do well to remember. First, the social worker has to mediate between the individual and the community with real responsibility to the latter, while the doctor, in his capacity of private practitioner at any rate, is more concerned with the former. Secondly, the social worker is concerned with the present situation and is not primarily concerned with causal factors. These are the province of the psychotherapist, and the social worker is not a psychotherapist.

Mrs. CLAIRE LOEWENFELD, in response to public demand, has prepared a set of printed leaflets on *Britain's Wild Larder,* giving practical directions on the gathering and preparation of wild plants, herbs, fruits, and berries, many of which are rich in vitamins and agreeable flavours. There are three leaflets under the general heading "Wild Plants and Herbs" (price 3d. each); three leaflets on "Wild Fruits and Berries" (price 2d. each); and a third edition of the author's earlier leaflet on the collection, preparation, and use of wild rose hips (price 2d.). The leaflets can be obtained at the leading London bookshops or by direct application to Mrs. Loewenfeld at Hedgerose, Buckland Common, near Tring, Herts. The whole set will be sent for 1s. 6d. post free; the postage on individual groups of leaflets is 1d.

Preparations and Appliances

WATER CHLORINATION OUTFIT

We have received from Pond's Extract Company, Ltd. (Perivale, Greenford, Middlesex), samples of their emergency outfit for water sterilization. A solution of sodium hypochlorite containing 2.5% of available chlorine is provided in glass ampoules, the usual size containing 5 c.cm., which is enough for 2 gallons of water. The ampoules being hermetically sealed, deterioration is prevented, and their tapering ends are easily snapped off when they are required for use. The outfit includes tablets of sodium hyposulphite for neutralizing the chlorine after disinfection in order to make the water palatable.

Boots Pure Drug Co., Ltd., have put on the market half-gramme tablets of sulphaguanidine, the new sulphonamide for treatment of bacillary dysentery and for prophylaxis before operations on the colon and rectum.

COMPLACENCY IN ANAESTHESIA?

There are perhaps few subjects that lead to such energetic and informed discussion in our columns as anaesthesia. The shortest note, for example, on ether convulsions is followed by letters which far exceed in length the original communication. The high drama of bringing back to life by cardiac massage a patient who has died on the table inevitably evokes letters of praise and of criticism. In fact the recording by Mr. Hamilton Bailey of his unusual experience, and the subsequent interesting recital of his experience by Major John Nicholson, provoked Dr. John Elam to wonder whether anaesthetists were not getting too complacent in accepting with apparent equanimity a death rate on the table of between 1.3 and 1.8 per 1,000. He made what seems to be a useful suggestion—namely, that the Association of Anaesthetists might carry out an investigation into the relative safety of the various anaesthetics now used in general surgery and so lead to an assessment of their indications and contraindications. Later correspondents have renewed several old challenges. Dr. Massey Dawkins offered some slight correction to the view that complacency in anaesthetics may exist by giving his experiences of general anaesthesia carried out in the periods 1921-5 and 1931-5. In the first period deaths on the table amounted to 4.03 per 1,000, and in the second to 2.3 per 1,000. It is as well to remember that a death "off the table"—e.g., from subsequent lung complications—may also in part be the fault of the anaesthetist. But the part of the surgeon in such catastrophes must not be ignored: by faulty judgment in the choice of operation, by an operation entailing too severe a loss of blood, by heavy handling of viscera, he may be responsible for post-operative complications unjustly laid at the door of the anaesthetist.

But there is one theme that has recurred in this and other correspondence in our columns during the past few years—namely, that the standard of anaesthesia in this country as a whole is unsatisfactory. If this feeling is indeed widespread, then Dr. Elam need have no fears about complacency in the specialty which he combines with general practice. Indeed we may hope that complete satisfaction will never be reached, for such a state leads to stagnation of ideas and of effort. And the successful introduction of new techniques, new modifications of old techniques, new apparatus, new agents, all show that the specialty of anaesthesia is as alive to its opportunities and responsibilities as any other branch of medicine. The modern anaesthetist is indeed becoming conscious of the fact that his work is that of applied physiology, and it is, we believe, this change of attitude which has made both for advance in the subject and for the critical attitude towards it that has so healthily developed. The good is the enemy of the best; and if the level of the best is high and that of the good not always very, very good, then comparisons between different groups are apt, as Dogberry said, to become "odorous." No one can get away from the fact that experience teaches. It is inevitable that the occasional anaesthetist has come in for criticism, and that the whole-time anaesthetist seeking perfection in an imperfect world should wish all anaesthetics for conditions other than minor ones to be given by medical men with special experience or a special diploma.

We believe that all the wrongs there are in the situation can be traced to the fact that medical education has not kept pace with the innovations that have flooded medical practice during the past fifty years. The developments of modern anaesthesia and modern surgery have gone hand in hand, each aiding and abetting the other. The higher the art of the anaesthetist, the more bold can the surgeon be in his exploration of new fields; and the adventurous and imaginative surgeon inevitably stimulates his anaesthetic colleague to introduce new measures that will enlarge his scope. A medical student standing on the outer fringe of an admiring circle in the operating theatre must view the modern anaesthetist somewhat as the apprentice in the street used to view the mediaeval alchemist. If his lot is that of the bulk of the profession—namely, to become a general practitioner—it is unlikely that he will ever preside over the mysteries of the McKesson. In practice what he wants to know is how to use the rag and bottle, or mask and bottle, with safety and efficiency, and how to give a gas without making the patient purple. And, too, we would make the plea that he should thoroughly master the technique of giving the intravenous anaesthetics such as hexobarbitone. First and foremost the general practitioner needs to have a thorough working knowledge of anaesthesia for minor surgical procedures. Secondly, he should be fully acquainted with the snares and traps that beset the giving of anaesthetics in the old-fashioned way for the occasional major emergency. Only too often he has to learn the rudiments of the art when engaged in actual practice, and if, indeed, the standard of occasional anaesthesia is lower than it should be, then the blame must be distributed between those who teach this subject, those who draw up the curriculum, and those who conduct anaesthesia. Sooner or later a carefully thought out answer must be given to the question, "How far does medical education as at present carried on in the medical schools of this country prepare the student for work in general practice?"

The immediate problem, as we see it, is how to reconcile the ideals of the whole-time staff anaesthetists of this country, who are second to none in the world, with the need for grounding the embryo general practitioner in methods which most of the experts have abandoned as obsolete. All are agreed that the curriculum is overcrowded, and the student has little time to learn the simpler anaesthetic techniques which he will be called upon to practise in small cottage hospitals and in emergency work in humble homes or factories or camps or ships at sea. A nodding acquaintance with modern apparatus will not help him then. Mr. Cecil Hughes, in his letter printed on June 6, says that "the advent of 'machines' has undoubtedly led to a deterioration in the anaesthetic education of our students, a very large number of whom when qualified have probably never seen, let alone given, chloroform anaesthesia. If every student were taught to give a mask anaesthesia with C.E. mixture . . . he would certainly be more fitted for general practice, and for work in the smaller hospitals where these machines are not always available. . . . Chloroform has to be, and always will be, used at times for various reasons and circumstances, and it is deplorable that students should qualify without being used to its administration." It is too much to expect the new graduate to be a competent anaesthetist, but elementary instruction in anaesthesia should never be regarded as a mere matter of getting signed up: teachers and examiners should insist on a minimum standard of knowledge upon which experience can build—*and the maximum amount of practice in the simpler methods*. But, whatever method of anaesthesia is taught or attempted, it remains true that any technique can be dangerous if the user is incompetent. This raises the question whether the general practitioner of only average anaesthetic experience is fully competent to anaesthetize patients requiring a major operation. The practitioner who is frank with himself will surely admit that his competence cannot be as great as that of the man who devotes himself exclusively, or at least largely, to mastering special techniques and acquiring detailed knowledge through special study and research. It is self-evident that the more perfect the anaesthesia the better will be the operating conditions for the surgeon; and a surgeon will always do better when he works with an anaesthetist who understands his ways and whose skill as an anaesthetist he fully trusts. The close relationship between surgeon and anaesthetist, a subject dealt with in an interesting article by N. A. Gillespie,[1] is of the highest importance to the object of this relationship—the proper treatment of the patient and his ultimate recovery. To this end everything else must be subordinated, although, human nature being what it is, "at some time or another," as Gillespie says, "we have all been guilty of allowing our personal pride to supplant the patient's interest." There is one aspect of this which has worried not a few surgeons and anaesthetists, and that is the occasional insistence of the general practitioner that he shall administer the anaesthetic to a private patient of his about to undergo a major operation. The surgeon who counter-insists that he must bring his own anaesthetist is unlikely to have his services called upon a second time, for obvious reasons. It is not suggested that such a point of disagreement between practitioner and surgeon is common, but at the same time it is useless to blink the fact or to evade it by soft words. The occasional anaesthetist in general practice must recognize his limitations, perfect himself in anaesthesia for minor conditions, and seek to employ a specialist anaesthetist for major and difficult operations just as he seeks to employ a surgeon with special skill to perform them.

As Gillespie brings out in his article, during recent years there has been a most fruitful revival of interest in, and original work on, anaesthesia. There is need, he says, for the keeping of records by anaesthetists, so that analysis of such records will enable them to give a more convincing answer to the usual question in the operating room, "Is he all right?" He argues that the anaesthetist with special knowledge should be used in diagnosis and treatment of post-operative complications; for example, his familiarity with the technique of intubating the respiratory passage enables him to treat atelectasis by suction drainage. The anaesthetist's work does not in fact begin and end in the theatre, but should begin and end at the bedside before and after operation.

Largely through the efforts of the Association of Anaesthetists in this country, the English Royal Colleges have instituted a diploma in anaesthetics, now rapidly becoming recognized as a necessary qualification for whole-time staff appointments. It is to be hoped that the examination for such a diploma will not become too theoretical, and will lay greater stress on practical knowledge, practical experience, and practical ability. The creation by Lord Nuffield of a Chair of Anaesthesia at Oxford has done much to raise the status of the specialty, and will no doubt bear increasing fruit in applied research.

APPLIED PSYCHOLOGY IN THE ARMY

It has become all too obvious these days that the waging of successful war is essentially a matter of applied science. Victory is likely to rest not so much with the big battalions as with the side that applies scientific knowledge and methods most thoroughly in all possible fields of endeavour. Nevertheless this does not mean that the individual has ceased to be important. On the contrary, he has become even more important. Successful war more than ever depends on the intelligence, initiative, and courage of the individual soldier.

Can science be applied in some way to the individual, and, more especially, can it be applied to the selection of leaders, who have the greatest responsibility of all? An attempt has been made by the British Army to answer this question in a very interesting and promising piece of work which has been under way for some time past. It was called into being partly as a means of reducing the wastage in officer training, as it was found that a certain proportion of those picked out for training failed to qualify for commissions, and the question arose whether the methods of selection for training purposes could be improved, saving thereby a considerable amount of time and effort. A refinement of this aim obviously consists in adopting methods, if they can be found, which will not only prevent failure but will choose the very best from the material available. The first unit for officer selection was established in Scotland and has now been working long enough to give that amount of confidence in the results which has justified the setting up of similar units in different parts of the country. The method consists in a study of the individual by a team of people consisting of psychiatrists, psychologists, and military testing officers, the latter being officers with military experience who live with the candidates during the three-day period of their residence at the unit, and who watch them perform a series of tests designed to elucidate their physical stamina, their behaviour in emergencies, and their ability to solve simple practical problems in the field. A central feature of the procedure is the psychiatric interview, which is designed to get a picture of the candidate's personality and leading traits of character and temperament. There is as yet no test or series of tests which will portray temperamental qualities in a more reliable way than the psychiatric biographical method. The psychiatrist's daily work consists so largely in the assessment of temperamental factors and resistance to stress, both internal and external, that he is well qualified to assess the probable reactions of the individual under war conditions. If the psychiatrist himself has had combatant military experience he is doubly equipped.

Intelligence testing is on a more systematic footing and is capable of application to a number of individuals at one time. Group testing of this sort is a routine at the unit, but the psychologists who are attached to it work all the time on possible improvements in method, and especially on tests which will throw light on some aspects of temperament; but such observations must always be dovetailed with the psychiatric survey, keeping the whole procedure essentially a clinical one. Each candidate spends between two and a half and three days at the unit, and the reports from the psychiatrists, psychologists, and military testing officers are collated at the end of that time and submitted to the president of the Board, who is a serving officer from a field unit, and in whose hands the ultimate decision lies.

The procedure thus briefly outlined has the effect, it is found, of giving a sense of satisfaction and fair play to the candidate for a commission. It aims very much at detecting fundamental qualities, independent more or less of education and upbringing, and so has the advantage of giving the chance to show his true form to a young man who may have lacked educational opportunities but may possess qualities of leadership. There are already indications that, because the selection procedure is now apparently an exacting one, considerable prestige is attached to successful emergence from the ordeal. This cannot but have a good effect on morale, both on the officer himself, who knows he has passed such tests, and on the men under him, who know that he has been able to survive such a careful method of selection. There are promising indications, also, that the wastage in officer-training may by this method be much reduced. Incidentally there is in this war-setting an anticipation of that principle of equality of opportunity which has been so much talked about with reference to post-war social legislation. Such efforts as are represented by this War Office experiment to introduce scientific method into the choice of officers are part of a pattern for the scientific organization of our fighting Forces. The Army Directorates responsible—the Directorate of Selection of Personnel and the Directorate of Army Psychiatry—will have the good wishes of everyone in their pioneer work in this direction.

MALARIA IN BRITAIN

An article in this issue by Prof. Warrington Yorke on malaria imported into this country in persons returning from service in endemic zones is particularly apposite at the present time. Such persons returning on leave to homes scattered throughout the British Isles may be taken ill suddenly with malaria, and in the absence of proper diagnosis and treatment are only too apt to die. Such a state of affairs should not obtain if the possibility, indeed probability, of malarial infection is adequately appreciated by the medical practitioners throughout the country. Under peacetime conditions, however, instruction on the disease to the undergraduate student was inadequate, because the condition was regarded as a strictly tropical entity. This view is at least open to grave objection in a maritime race; and, under conditions such as those which now obtain, it requires early amendment. It is gratifying to find that certain medical schools are taking steps to remedy an obvious defect by providing instruction on this and allied subjects for their students in the medical curriculum.

HYPERTENSION IN UNILATERAL RENAL DISEASE

It has been known for some years that unilateral renal disease may be found in patients, especially young persons, who have succumbed to hypertension. Such cases were occasionally mentioned before the work of Goldblatt,[1] and, later, that of Wilson and Byrom,[2] called attention again to the close relation between hypertension and kidney disease. This work, which has already been reviewed in these pages,[3] provided clinicians with the hope that cases might be found from time to time in which hypertension had been caused by disease in one kidney only and might therefore be amenable to cure by nephrectomy. The hope has been justified, and a number of cases have now been published in which nephrectomy has been followed by a return of the blood pressure to normal. The first successful case was that of Butler.[4] This was in a boy of 7 who developed unilateral pyelonephritis after removal of a renal calculus. The blood pressure gradually rose to 160/105, but returned to normal immediately after nephrectomy.

It is impossible in a short space to review all the cases which have now been published, and in any event they are difficult to classify. The most successful results have been obtained in children with hypertension, and the commonest cause has been some congenital abnormality of the kidney, with or without superadded infection. Much less satisfactory, as might be supposed, are cases occurring in elderly persons in which the aetiology of the hypertension is less certain and evidence of a completely normal kidney on the side not obviously diseased is less convincing. It is still difficult to decide what the indications for nephrectomy are. Abeshouse,[5] in a comprehensive but rather lengthy review, agrees with the criteria suggested by Schroeder and Fish—namely, that the hypertension should be of recent origin; that the renal lesion must be confined to one kidney; that the combined renal function must be normal; that retinitis should be absent; and that the hypertension must be persistent. These criteria are largely a matter of common sense, but a recent case published by Platt[6] shows that even in the presence of retinitis and papilloedema the operation may be justifiable, in fact life-saving.

So that the position may be clarified more exact observations are needed, and physicians and urologists should be on the alert. Every case of hypertension, especially in a young person, in which the aetiology is not obvious should have a thorough urological investigation. Conversely, the blood pressure should be taken in every urological case. Where persistent hypertension occurs with unilateral disease nephrectomy should be contemplated, not merely from the urological point of view but as a possible means of curing the hypertension.

ENDOCRINE FACTORS IN ACNE VULGARIS

Of late years the impression has become stronger that the aetiology of acne is more complicated than was formerly believed. Because the one undisputed fact about acne is that it makes its appearance almost invariably at about the age of puberty, the influence of the endocrine glands has been postulated by many as a factor in its aetiology. So common are an oily skin and acne in early adolescence that it has even been held that their presence is normal and their absence abnormal. The association between acne and puberty has naturally focused attention on the relation between acne and the sexual glands. Nevertheless, non-gonadal endocrines have also been incriminated by many observers. Dr. Lipman Cohen,[7] in a laborious and exhaustive review of the subject, concludes, firstly, that acne occurs with abnormal frequency in connexion with certain disorders of the endocrine system, such as tumours of the suprarenal cortex, and during the administration of androgens such as testosterone propionate. This has often been seen during its use for hypogonadism—but nevertheless certain authors recommend it as a treatment for acne. In an American prison 148 men were treated for acne by testicular implantation and 99 were said to have improved. But such opportunities rarely come the way of the dermatologist. Another factor often evoked to explain acne is a disturbed carbohydrate metabolism. But there seems to be little reason to believe that it is at all abnormal in acne, though Semon and Herrmann's results in the treatment of acne by injections of insulin are suggestive. Other disorders of metabolism which have been held responsible for acne in greater or less degree are changes in water metabolism, especially retention of water in the skin. The Suttons, father and son, describe acne as a "primary epidermal lipoidosis" and as a "pustular lipoidosis." The sheet anchor in their method of treatment is a low-fat diet, from which they claim excellent results. But another

American dermatologist, Becker, advises a high-fat diet to compensate for the calories lost in the reduction of carbohydrates that he advises. The more one studies the literature of this subject the more difficult it becomes to draw any clear-cut conclusions. The only real argument in favour of an endocrine aetiology is the regularity of its appearance at puberty and its ebb and flow with the menses. As regards treatment, Stryker and Bloom very appositely point out that the majority of articles praising endocrine therapy deal with series of fewer than ten cases each, usually without any control series—and Lynch reports that he obtained an improvement in 64% of his controls. In fact, the uncritical nature of so many reports confers no credit on clinical investigation.

BIOLOGICAL VALUES OF BREADS

The biological value of a bread comprises its content of protein, carbohydrate, vitamins, and salts, and also its digestibility. Some of these factors can be determined chemically, some by experiments on animals; but some must be determined by experiments on human subjects. Murlin *et al.*,[1] by experiments on ten healthy male subjects, have lately compared three whole-wheat breads, one whole-wheat cereal biscuit, and three white breads for digestibility and biological value of proteins. They had six-day feeding periods, twenty-four-hour urine analyses on the last four days, and analysis of faeces in one lot for the full period. They found that the whole-wheat breads gave lower true digestibility values for the protein than the white but produced higher biological values. Making bread with "high vitamin" yeast or eating extra B-complex vitamins separately seemed to improve the biological value of the proteins. The apparent digestibility of carbohydrate and fat was the same whichever kind of bread was eaten. Thus the "indigestible residue" of the whole-wheat products did not, in this experiment, have the effect usually ascribed to it. Macrae *et al.*[2] have fed human subjects over a period of twelve days with a diet of bread (white, fine wholemeal, or coarse wholemeal), margarine, milk, marmalade jelly, and mild ale. During the last seven days, total energy, nitrogen, and fibre of the food consumed and of the faeces excreted were determined. The average net absorptions of the energy, nitrogen, and fibre of the white bread were 96.1, 91.0, and 65.8%, of the fine wholemeal bread 86.9, 85.3, and 14.0%, and of the coarser wholemeal bread 87.1, 85.7, and 9.7%, respectively. The intake of nitrogen per 100 g. wholemeal bread eaten was 2.91 g., and of white bread 2.7 g., but this advantage was neutralized by the larger amount of nitrogen in the faeces from the wholemeal bread. The degree of fineness to which the wholemeals were ground made no significant difference to the utilization of the energy or of the nitrogen they contained. Krebs and Mellanby[3] have found, also by experiments on human subjects, 94% utilization of calories and 89% digestibility of protein in wheatmeal bread of 85% extraction (the national wheatmeal bread). From a comparison of these with Macrae's figures they argue that the digestibility of both 75% extraction flour (white) and national wheatmeal is much greater and the differences between them much smaller than was assumed by Wright[4] when he put forward the opinion—"that the adoption of the wholemeal loaf would not result in any appreciable saving in the energy content of the nation's dietary, while it would cause a significant reduction in both the quantity and quality of protein available for human consumption." Kodicek[5] has concluded from various calculations that the eating of wholemeal bread instead of white bread, in conjunction with the average dietary available to-day, would raise the intake of nicotinic acid from the minimal requirement (8 to 10 mg. a day) to about 12.3 mg. Wheatmeal bread, he says, would be almost as effective. Thus, from the human standpoint, evidence is accumulating of the superiority of wheatmeal over white bread.

FERTILITY STATISTICS

A very limited edition of Part II (Civil) of the Registrar-General's Review of England and Wales, 1938, has been printed for official use. The publication can be consulted at Somerset House or at Terra Nova, Lancaster Road, Southport. A few copies are available for temporary loan to approved persons having an acknowledged interest in vital statistics, and application should be made to the Southport office. The volume contains the usual tables of population, births, marriages, etc., but the principal interest is in the new feature—the first analysis of the information bearing upon the fertility of women in England and Wales, collected under the Population (Statistics) Act of 1938: the data relate to the second half of that year.

Almost one-third of the mothers of legitimate children during this period were aged 25–29, and nearly one-quarter were in each of the adjacent age groups 20–24 and 30–34. It is interesting to note that the intervals between marriage and the first birth in 1938 show that about 40% of women who married before 20 years of age must have been pregnant before marriage, about 30% of those who married at 20, about 20% of those who married at 21, and 8% of those marrying at 30–34. Half the mothers of illegitimate children were under 25. When the number of children born was related to the number of women in the various age groups, a rapid decline with increasing age was shown in the legitimate birth rate. At ages 15–19 the proportion of married women producing a child was one-half, at ages 20–24 the proportion was one-quarter, and in the 35–39 age group the rate had declined to one woman in twenty. The trend of the illegitimate birth rate, by ages of mother, did not decline continuously: the rate was highest at 25–29 years, but there was little change between ages 20 and 39. The first confinements formed 42% and the second 25% of the total confinements. Fertility in 1938 declined continuously as the duration of marriage increased from 0 to 10 years. Fertility immediately after marriage has declined since 1911, by one-third for women marrying at 20–26, and by one-quarter for those marrying at 27–30. Statistics of twins and triplets are given for the first time. One of every 42 children born was a twin, and one in every 3,873 a triplet. The risk of a confinement producing a multiple birth increases with age of mother up to ages 35–40, where it is a maximum. The report shows that the "adjusted net reproduction rate" was 0.84, or 16% below the necessary standard for reproducing the population. If an ultimate decline in the native-born population is to be averted an increase of 19% in the reproduction rate will have to take place. Discussing how this increase might be brought about, the Report states that in 1938 there were in this country 275,000 spinsters aged 40 to 44.

The Prime Minister of Turkey, Dr. Refik Saydam, who died suddenly at Istanbul on July 8, had made his name as a physician and personal medical adviser to Kemal Ataturk before entering political life as Minister of Health after the establishment of the Turkish Republic. He showed energy and great administrative skill in devising and carrying out hygienic measures. The health services of Turkey owe much to his statesmanship and creative vision.

NUTRITION OF EXPECTANT AND NURSING MOTHERS

A special committee set up by the People's League of Health in July, 1935, to investigate and consider the nutrition of expectant and nursing mothers in relation to maternal and infant mortality and morbidity has prepared an interim report of its research. This document is signed on behalf of the special committee by its chairman, Prof. James Young, by Dr. C. O. Hawthorne, chairman of council of the League, and by Dr. W. C. W. Nixon, medical secretary of the special committee. The report, with minor omissions, is printed below.

The committee has completed a survey which involved the study of the records of over 5,000 women and which it believes to be more comprehensive than any similar investigation previously carried out. The League has been fortunate in enlisting the co-operation of 10 London hospitals.

A Statistical Survey

The investigation was carried out from March, 1938, to the end of 1939, and involved the keeping of accurate records in the case of 5,022 women and the compilation of 324 statistical tables. This was rendered possible only by the generous and unstinted services of the staffs in the various hospitals and of the statistical member of the committee (Mr. W. T. Russell) and his assistants. The People's League of Health is indebted to three commercial firms—Vitamins Ltd., Crookes Laboratories, and Roche Products Ltd.—for free gifts of the vitamin and mineral elements required.

The main investigation was planned to show whether additions of the appropriate vitamins and minerals to the daily food would have a beneficial effect on the course of pregnancy and labour and on the newborn child. In order to obtain some information concerning the type of diet consumed by the group of women to be studied, an inquiry was carried out among expectant mothers attending four of the hospitals which collaborated in the test. Included among these patients were some of the women enrolled in the investigation. It was not found possible to make a detailed dietary survey, but nearly 1,000 women collaborated by filling in questionaries which gave a record of the food they had eaten during a week. It is recognized that this procedure was at best a rough-and-ready method of assessing food consumption, but there were good reasons for believing that it would give some evidence of the nutritional level of the women during the experimental period. Analysis of the records showed that, in general, there was no marked deficiency of first-class protein among any of the women answering the questionaries.* As regards minerals, a shortage of calcium was noted in about 70% of the women, most of whom were consuming insufficient milk and cheese. Iron deficiency was even more serious, only 2% having a satisfactory intake.

Vitamin and Mineral Deficiencies

The deficiency of vitamin A was the most common, this being anticipated from comparison with other pre-war data: rather more than half of the women were taking less than they required. Vitamin B_1 deficiency was not nearly so marked, and, generally speaking, the diets were not badly defective in this respect, but nearly half the women were not obtaining as much as was really desirable. Vitamin C shortage also affected about 50% of them, but once again the magnitude of the deficiency was not nearly so great as had been expected. The general impression was that the women were on the average better nourished than had been expected from a direct comparison of data derived from previous dietary surveys of comparable groups of the ordinary population. It was clear that in a number of cases they were following advice given at the ante-natal centres and that fresh fruit and eggs frequently entered into their daily diet. The same was true of milk. The women stated that they were taking these foods especially because they had been advised that the health of their babies would thereby be improved. There were, however, instances in which the dietaries were grossly defective.

The committee next decided upon the amounts of vitamins and minerals required to make up the deficiency in the above respects. The daily supplements used for the experiment were: Saccharated iron carbonate, 18 gr. (1.1 g.), equivalent to 0.26 g. ferrous iron; calcium lactate, 30 gr. (2 g.), equivalent to 0.26 g. calcium; minute quantities of iodine, manganese, and copper; adsorbate of vitamin B_1 containing all factors of the B complex B_1 content standardized at 200 international units per g.), 15 gr. (1 g.); vitamin C (ascorbic acid), 100 mg.; halibut-liver oil (vitamin A, 52,000 I.U. per g., and vitamin D, 2,500 I.U. per g.), 6 minims (0.36 g.).

In each hospital the women enrolled at the ante-natal clinic were divided into two main groups by placing them alternately on separate lists. The women in one group received the supplements, while those in the other were kept as controls. Within each of these groups the women were further classified into (1) women pregnant for the first time; (2) women with a history of one or more previous pregnancies. And again each of these two groups was subdivided into: (*a*) women under 25; (*b*) women between 25 and 30 years; and (*c*) women over 30 years. All women who were not in good health were at the outset excluded from the experiment, also women whose delivery was expected in less than 16 weeks.

The groups of important records thus obtained have been analysed by the statistical member of the committee and his assistants, but the extent of the material collected and the exigencies of the war have made it impossible for the committee to prepare a full report at present. In view, however, of the importance to the community of certain facts which have emerged it has been decided to issue this preliminary report.

Toxaemia of Pregnancy

At the start of the research it was decided to regard as toxaemic (*a*) cases which exhibited hypertension—a systolic blood pressure of or above 140 mm. Hg or a diastolic pressure of or above 90 mm. Hg—with or without albuminuria, oedema, etc., and (*b*) cases in which there was no hypertension and in which the diagnosis was based upon albuminuria.

In the 1,530 primigravidae who received the supplementary diet the toxaemia rate on the above standard was 27.1%, while in 1,512 primigravidae who did not receive the supplementary diet the rate was 31.7%—the difference being 4.6±1.7%. This result was due to the dominating influence of the statistical experience of women aged 25-30, in whom the difference was 7.7±2.6%. At the younger and older ages the difference, although still favouring the treated groups, was statistically unimportant. In multiparae there was no difference between the two groups, the incidence of toxaemia being 21.8% in both 980 treated and 999 controls.

Within recent years it has come to be recognized that a diagnosis of toxaemia cannot be based upon hypertension by itself, as this frequently connotes not a true or specific pregnancy toxaemia but an essential hypertension. The exclusion from the above groups of cases with hypertension as the sole clinical condition leaves those women in whom the diagnosis of toxaemia is based upon albuminuria, oedema, etc., with or without, but generally with, hypertension. This treatment of the figures may result in the exclusion of some cases in which the hypertensive state is due to toxaemia, but any such disadvantage is offset by the fact that, apart from any possible differential benefit derived from the supplementary diet in one group, each group is being similarly treated. It has the advantage of segregating for special study those cases in which the diagnosis of toxaemia rests on a reasonably secure foundation.

On this basis the primigravidae who received the additional dietary ingredients had an incidence of toxaemia of 5.4%, while in the primigravidae who did not receive any additional diet the percentage was 7.4. The difference and its standard error was 2.0±0.9, which means that the odds are nearly 40 to 1 against such a result being obtained by mere chance. The figures were also favourable to the parous women, but not to a significant degree, the percentages being 3.6 and 5.2 respectively, the difference being 1.6±0.9 (see Table). These results are striking, and indicate that the women receiving the special diet are protected against the risk of toxaemia in a ratio which is almost 30%. When it is remembered that, next to puerperal sepsis, toxaemia is the most important cause of the maternal death rate (about 20% of the total) in addition to being one of the most fertile sources of chronic ill-health after childbirth, the findings of the committee assume a significance which it is hardly possible to overestimate. This investigation has been carried out in the London area, in which it is known that the incidence of toxaemia is low. A reduction of 1.8% has been obtained. If a similar reduction could be obtained for the whole country it is estimated that on the basis of the annual number of births—approximately 600,000 in the immediate pre-war years in England and Wales—there would be 10,000 fewer cases of toxaemia in the year.

---

* It was not found practicable, owing to the restricted facilities available, fully to analyse in terms of calories, grammes of protein, units of vitamin, etc., the diet of the women whose food consumption was investigated. A scoring system was therefore adopted by which arbitrary values were given to express the daily consumption of the more important foodstuffs such as milk, butter, wholemeal bread, fresh vegetables, fatty fish, fruit, eggs, etc. By making a sum of the weekly score for appropriate foods, approximate estimates could be made of the intakes of first-class protein, vitamins, minerals, etc., while from a general summation was obtained a picture of the diet as a whole. This admittedly rough-and-ready procedure sufficed to reveal any marked deficiencies in the diet.

In a further classification based upon the criteria generally accepted for "pre-eclampsia"—namely, hypertension with albuminuria, oedema, etc.—the following toxaemia rates were obtained: treated primigravidae 4.51%, untreated primigravidae 6.42%, the difference being 1.91±0.82; treated multiparae 3.16%, untreated multiparae 4.60%, the difference being 1.44±0.87 (see Table).

Pregnancy Toxaemia

	No. of Women	Hypertension only		Albuminuria with or without Hypertension		Hypertension with Albuminuria, etc. (Pre-eclampsia)	
		Cases	%	Cases	%	Cases	%
Primiparae							
Treated	1,530	332	21·7	83	5 4	69	4 51
Controls	1,512	368	24·3	112	7·4	97	6 42
Difference (C–T)		2·6 ± 1 5		2·0 ± 0 9		1·91 ± 0·82	
Multiparae							
Treated	980	179	18 3	35	3 6	31	3·16
Controls	999	166	16·6	52	5 2	46	4 60
Difference (C–T)		− 1·7 ± 1·7		1·6 ± 0 9		1·44 ± 0 87	
Total	5,021	1,045		282		243	

The Infant

Prematurity.—The committee found evidence, which it regards as statistically significant, of benefit to the infant from the improved diet of the pregnant mother. It finds that the prospects of a woman carrying her child to term are improved by the diet. Thus, out of 1,529 primigravidae receiving additional diet, in 308, or 20.1±1.10%, the pregnancy ended prematurely (i.e., before the 40th week), while in 1,512 primigravidae who did not receive any addition prematurity occurred in 361, or 23.9±1.10%. The corresponding figures for the multiparae were almost exactly similar to those for the primigravidae—namely, 20.1±1.33 and 24.2±1.33. The differences in both instances are greater than mere chance fluctuations. This result—the relatively greater proportion of term deliveries among the treated women—is of importance, particularly in view of the fact that, according to the Registrar-General's statistics, 50% of infantile deaths under one month are due to prematurity.

Weight of Baby.—For primigravidae of all ages the difference is slight—7.18±0.03 lb. for the treated as against 7.17±0.03 lb. for the controls; but a similar comparison for age 30 and over reveals a wider range, the treated being 7.17±0.7 lb., as compared with 6.99±0.07 lb. in the babies of the control mothers. The difference here is 0.18 lb., which approaches significance. In the multiparae of all ages the difference between the birth weight is −0.07±0.05 lb., which is not significant; but the trend of the values favours the treated women, as in 3 out of the 4 age groups their babies were slightly the heavier.

There is evidence of a considerable difference in the average birth weights in different hospitals. In hospital B the mean value was 6.98 lb. for babies of primigravidae, as against 7.22 lb. and 7.42 lb. in hospitals G and J. The corresponding weights in the multiparae class were 7.43 lb., 7.62 lb., and 7.89 lb. The differences between these mean weights are statistically significant. These wide deviations in the average birth weight of babies born in different London hospitals raise questions which merit further investigation.

The committee could not find any evidence to support the view that the addition of the vitamin and mineral elements to the dietary affects in any appreciable degree the risk of the development of fever and sepsis after childbirth. Nor did it find any appreciable influence on the character and duration of labour.

Benefits of a Well-balanced Diet

In directing attention to the significant benefit both to mother and child of a well-balanced diet in the ante-natal period, the committee would at the same time emphasize some considerations which make it likely that in its nature the investigation could not be expected to discover the full extent of this benefit. The committee had to avoid the risk, peculiarly attendant on this class of investigation, that materials (vitamins and minerals) intended for the mother would be diverted from her diet and added to the general family stock. For this reason the substances were given in tablet and capsule form, and, as was to be expected, some women defaulted. It may further be urged that the full value of such protective substances can be realized only when they are given in the form of naturally occurring foods. For these reasons the committee feels that there is sound reason for the view that the results of the investigation, valuable and significant as they are, should be regarded as pointing to the minimal rather than to the maximum advantages to mother and child of a well-balanced maternal dietary. It should also be mentioned that the statistical results which have been obtained concerned women whose basic diet was in all probability somewhat better than that of similarly constituted groups of women at the present time.

This comprehensive and controlled investigation furnishes for the first time clear evidence on questions which have long been in dispute. In so far as the results demonstrate the influence of a well-regulated diet on the health of mothers and on the development and well-being of their infants, they are of great national importance. Further, this message is addressed to all sections of the community, for it is not solely among the poorer classes that defective nutrition is prevalent. At the same time, since poverty and malnutrition march hand in hand, and since the poorer classes are relatively the most fertile, it follows that the ravages of faulty maternal nourishment fall with tragic emphasis on the mothers in poor homes and on their children.

Correspondence

"Positive Health"

SIR,—The salutary and timely protest in your annotation (July 4, p. 16) that ability in one specialty does not necessarily confer ability to speak with authority in another—*vide* the Socialist Medical Association's resolution in favour of a "second front"—might equally be applied to the subject so pertinently raised by Mr. A. R. Jordan in his letter in the same issue (p. 22). Do not the medical profession, specialists in the care of the sick, act in the same manner when they pose as authorities on "positive health"? No doctor, the school medical service excepted, is in a position to study any section of the populace other than those who constitute themselves "patients." Sickness must come to the doctor before he is empowered to act; he must wait the patient's pleasure. How then can such experience qualify medical men to be experts on health or even on fitness?

In *Biologists in Search of Material* (Faber and Faber, 1938) we gave the results of complete overhaul, including laboratory, biochemical, and physical examinations, of the 1,530 individuals over 5 years of age comprised in 500 families. These results were as follows.

8% with acknowledged disease—i e, aware of their disorders—receiving medical treatment;
24% with acknowledged disease *not* receiving medical treatment;
59% with disorders discoverable by us, but the presence of which was either ignored by or unknown to the individuals, and who were, therefore, also not under medical care;
9% without any disorder discernible by the examiner.

These families were taken from among those presumed to be a healthy populace. From these figures, which we have no reason to believe would vary to any great extent whatever sample of the normal public was chosen, it will be seen that the medical profession has a very long way to go before it has so organized its own activities as to bring the benefits of modern medical science to all those in need of them—namely, all the disordered. Not until this is done will the borderland between health and sickness bring them legitimately and naturally to the brink of the subject of health.

The fact that the majority of those with untreated disease are ambulatory "cases," though not necessarily of minor disorder, perhaps affords a partial explanation of how it is that they have not come within the cognizance of the medical profession. The man in the street is not such a fool as he looks. He knows that the hospitals and clinics have a "corner" in scientific instruments, without which he naturally, and perhaps rightly, presumes that the medical services cannot do justice to the nice demands of non-incapacitating disorder. But he also knows that the circumstances of organization of these hospitals and clinics will almost inevitably immobilize him should he go near them. It is thus in some measure the intelligence of the man in the street which is keeping him from seeking the help that he believes modern medical science to hold for him. Only two things can put this right. One is to furnish the practitioner with the tools and instruments which as a student he has been trained to use. The other is to reorganize the setting of the hospital out-patient facilities and to sweep away the obsolete spirit of patronage in which they are offered.

Even these reforms will only touch the fringe of the problem of the treatment of disorder. Nothing but periodic overhaul can disclose the disorders of those unaware of their presence. Fifteen years of experience directed expressly to this subject has taught us, however, that periodic overhaul of those unaware of their disorders must essentially be in the nature of periodic *health* overhaul, not periodic *medical* overhaul—that is, it must primarily be directed to the assessment of the capacity of the individual for health rather than in the nature of a search for his disorders. Though by periodic medical overhaul we might eliminate the physical disorders of the individual, we should be running a serious danger of creating psychological disorders.

Our experience has shown us that for periodic overhaul to be of maximum and continuing value it must be: (1) overhaul of the family, not of the individual, who is but a "limb" of the family; (2) it must be accompanied by circumstances which enable the family, the individuals of which have had their disorders removed, to move out of the environment that has created these disorders into one in which they may live and function more fully—i.e., in health. For this reason, in 1935 the Pioneer Health Centre, to cater for 2,000 families, was opened as a full-scale experimental research into the nature and cultivation of health. I would claim with Mr. Jordan that it is only through the old methods of long, laborious, and completely unprejudiced research that "personal hygiene can be erected into something of a science."—I am, etc.,

INNES H. PEARSE, M.D.,
Co-Director, Pioneer Health Centre, Peckham.

Planning a Hospital Service

SIR,—For sound planning it is necessary to decide the primary interest for which service is needed and to allow this to determine the main form of the plan. All proposals will then be judged from the point of view of this primary interest: much discussion may be saved and confusion avoided thereby.

In the matter of hospital provision what is required is primarily a service which is adequate for the treatment of members of the community suffering from serious illness, and a system that will ensure, so far as possible, that wherever A and B go or are sent they will be offered the skill and care they need. The value of all proposals as to the form of the hospital service should be tested against this principal requirement; for example, the question when and where it may be in the public interest to maintain the distinction between "voluntary" hospitals and those controlled by public authorities.

The system of the future must perform certain secondary functions; it must, for example, provide facilities for medical education. The call for such secondary functions should not, however, determine the main structure of the system; everywhere the primary question should be, "What does the public need?" It is when attempts are made to put first what should come second that conflict and confusion come into the discussion. If special institutions are built or chosen with an eye, primarily, to providing conveniently placed medical academies, they may well fail to satisfy the fundamental need of a medical school—namely, a varied and extensive field for clinical instruction—unless the compulsory transfer and allocation of patients by office rule is to be a feature of the future system.

On one matter there will certainly be general agreement between those who have made a study of administration and the medical profession. If the service is to be equal to its difficult task, administration must take counsel with the practitioner and give him the utmost possible freedom in his work and its development. In no public service would the suffocation of personality by iron regulation and inquisition have more damaging effects upon quality.—I am, etc.,

Liverpool. K. W. MONSARRAT.

The Planning Commission's Report

SIR,—I read the proposals of the Planning Commission with great interest, and would like to offer some comments on them. I should state at the outset that I, personally, am in favour of a State Medical Service.

I believe that any radical change in the organization of the medical services should be undertaken only after a plebiscite of the whole profession, including those in the Services. One can hardly differ from that part of the report which points out the faults of the present services and the general principles of what is required to correct them. I wish to criticize three of the suggestions made in the detailed scheme.

The first is that close liaison between the general practitioner and the hospital is not envisaged, nor is the need for it stressed enough. I believe this is because the proposals are not for a completely integrated and unified service. Secondly, since a capitation fee is retained the major evil of the present panel scheme is retained—namely, the inability of the doctor to act justly, according to his lights, toward his patient for fear of offending him and losing financially by a transfer. I believe that abuses of this kind would be worse under a collective scheme than now. Thirdly, the present unsatisfactory contributory hospital scheme is to go on. A recent case came to my notice of a man who contributed for 20 years to the local hospital, and never inside, then retired. His contributions lapsed; he had to go into the hospital for three months, and received a bill for over £37. I would suggest in conclusion that we send a deputation *of doctors who can speak Russian* to study the State service in the U.S.S.R.—I am, etc.,

T. D. CULBERT.

SIR,—The Kensington Division of the British Medical Association would like to record their appreciation of the monthly articles that have appeared in the *Supplement* for the benefit of Study Groups, and of the masterly survey of the problems confronting the medical profession together with their possible solutions as set out in the Interim Report of the Medical Planning Commission (*Journal*, June 20).

The Kensington Division, which, like other Divisions, formed a Study Group to discuss the preliminary details set out in the monthly articles, have been so impressed by this report that they have decided to discuss it "paragraph by paragraph." It is hoped that after 6 to 7 weekly meetings, of which 3 have already been held, the Division will be in a position to give precise answers to the questions asked at the end of the report.—I am, etc.,

H. STEPHEN PASMORE,
Hon. Secretary,
Kensington Division, B.M.A.

Use of the Term "Orthopaedic"

SIR,—I should like to put the case for a more restricted use of the term "orthopaedic." The O.E.D. gives 1840 as the date for the first use of the word in England, but in 1828 Delpech (Montpellier) used the adjective "orthopaedique" with precision as being concerned with the correction of deformities in childhood. In the latter half of the 19th century the word came to include adult deformities, and that remained its meaning till some 20 years ago. Since then the term has been extended by many to include the whole of traumatic surgery of the locomotor system, and it is held by some to embrace all forms of disease of the same system.

This arbitrary misuse of a term is difficult to justify. So far as I know a similar extension of the meaning of "orthopaedic" has not found favour on the Continent and is disputed in the U.S.A. I will give two concrete examples of the disadvantages attached to this lack of precision in the use of the word. First, its employment in Service instructions leads to ambiguity in their interpretation: does the term refer in a particular instance to the treatment of deformities, of fractures, or is it to be extended to include all injuries and diseases of the locomotor system? Secondly, if the latter interpretation is accepted, the use of the word "orthopaedic" in the description of surgeons suggests that only such surgeons can properly treat the wide range of conditions mentioned above, whereas it is well known that many surgeons who have but limited knowledge of orthopaedics in the 19th century sense are fully competent to deal with, and do in fact treat, injuries and diseases of the locomotor system.

It would appear that there is a tendency to include under the term "orthopaedic" at least two distinct branches of surgery—viz.: (1) the treatment of deformities; (2) the surgery of acute injuries to the locomotor system. The first is mainly concerned with the processes of growth; the second with wound infection and the processes of repair.

There is certainly no excuse for the toleration of this looseness of nomenclature. The term "orthopaedic" should be restricted to the first branch. I doubt if any special label need be sought for the second, as it is essentially a branch of general surgery.—I am, etc.,

Cambridge C. MAX PAGE.

Tetanus after Sulphonamide Treatment of Cavities

SIR,—I wish to correct certain statements in Dr. E. C. Atkinson's letter (July 4, p. 24).

I operated on this woman on April 13 and removed a large left pyosalpinx which was adherent to the bladder and to the intestines in the pelvis. In separating the pyosalpinx from the bladder some pus escaped into the pelvic cavity. Otherwise the abscess was removed whole, but the prolonged pelvic peritonitis from which the woman suffered had produced extensive non-purulent inflammation of the peritoneum over the intestines, and for this reason sulphapyridine powder (15 g.) was sprinkled on to the pelvic floor after the cavity had been swabbed as dry as possible. A medium-sized rubber tube was inserted down to the site of the pyosalpinx and was not removed until the third day.

This case formed one of a series of peritoneal infections in which the effect of sulphapyridine powder was being tried out by several surgeons. The patient progressed satisfactorily until the eighth day, when she developed trismus of the jaw, and in spite of immediate and continued treatment died of fulminating tetanus 26 hours later. An annotation on this case appeared in the *Lancet* of June 27.

I would stress that it is only a presumption that the infection was conveyed by the sulphapyridine powder. The container of the powder used at the operation was not available for examination after the patient died, although a toxigenic strain of *B. tetani* was isolated from the pelvis. Careful examination of other specimens of sulphapyridine and their cardboard containers failed to detect a toxigenic strain of *B. tetani*, although the cardboard of the containers gave cultures of several species of sporing and non-sporing bacteria. Among these organisms were some with the morphology of *B. tetani*, but since three pathologists failed to demonstrate toxin production, the identification of *B. tetani* is incomplete. It is clear, however, that the powder should be supplied in containers made of a substance which can be readily sterilized and not of cardboard derived from waste salvage material.—I am, etc.,

London, W 1 G. M. SANDES.

Urethral Instrumentation

SIR,—To one who, like myself, has been in general practice over thirty years, the letter of Mr. Gordon L. Bohn (July 4, p. 25) on the alleged dangers of a general practitioner passing a catheter might be annoying if it did not offer evidence of the fatuous and narrow outlook of the "one-specialty" man. I can assure Mr. Gordon Bohn that I have on many dozens of occasions passed catheters for acute retention, prostatic and strictural, and have never had cause to regret it—nor has the patient. And, no doubt, so have hundreds, nay, thousands of general practitioners all over the country. It is what we were taught to do—and how to do it—by teachers who knew their job and who also knew what emergencies we were likely to be up against when we started out into the world to earn a living as trained, qualified doctors.

Mr. Bohn's fear of what might happen to the kidneys from too rapid a decompression is surely beating the air. These dangers are well known to every trained doctor, and, therefore, guarded against. Mr. Bohn might, with credit, evince more fear (if he is given that way) of leaving a patient in agony with a superdistended bladder and all the ill effects likely to result from back-pressure on the kidneys, not to mention cardiac complications in an elderly prostatic case.

I note that Mr. Bohn informs us that in his opinion such a case—i.e., acute retention—should be admitted immediately into a hospital or nursing home—surely a counsel of perfection. Patients with retention quite often call the G.P. out of his bed at 2 a.m. or 3 a.m., and where, at that hour, and if in the country, can an ambulance be had straight away, or a bed obtained at a hospital or a nursing home, and if the latter, can the patient always afford the fee? Let us be realists and not frightened by bogies raised by specialists to impress all and sundry with the importance of their particular field of activity.—I am, etc.,

Bournemouth. VINCENT NORMAN.

The Expanding Pelvis

SIR,—Dr. Kathleen Vaughan (June 27, p. 786) has done good service in drawing attention to the importance in labour of the angle of inclination of the pelvic brim, for it is this angle which determines, to a large extent, whether the long axis of the uterus is perpendicular to the plane of the inlet. The larger the angle the more likely it is that the long axis of the uterus (and consequently its thrust) will be directed downwards and forwards against the pubic arch. An angle of about 90 degrees will favour a thrust downwards and backwards, which conforms to the direction of the pelvic inlet.

For the last two years I have measured this angle (together with the sacral angle) in every case referred to me for pelvimetry. I have records of over 200 cases, and hope that in course of time the number will be sufficient to make an analysis worth while.

In Dr. Vaughan's model the angle in extension corresponds to the average in my series. The extremes so far encountered have been 159 degrees and 84 degrees. It is probably a fact that the favourable influence of an optimum angle of inclination of the pelvic brim of 90 degrees may be offset by an abnormally small sacral angle.—I am, etc.,

Reading PAUL CAVE.

Increase in Hypoglycaemia

SIR,—Dr. E. Sutherland-Rawlings (June 13, p. 739) asks a question which has puzzled me from another aspect, and Dr. R. D. Lawrence (June 27, p. 802) only partly answers it. Formerly almost all my patients were balanced on a daily dose of protamine-zinc-insulin and soluble insulin in such proportions as Z.P.I.:S.I.=3:1, 5:2, and rarely 1:1. Now, however, many patients need more soluble insulin than protamine-zinc-insulin, and more and more are having to alter the proportion in the direction of Z.P.I.:S.I.=2:3, 3:5, and so on, in order to keep the blood sugar approximately normal during the twenty-four hours and to avoid hypoglycaemic reactions at night. At least one colleague has had the same experience.

If, as Dr. Lawrence suggests, the war insulin is stronger, it would seem to be only protamine-zinc-insulin, because the larger doses of soluble insulin do not cause reactions before midday; I have thought that perhaps the wartime soluble insulin contains some impurity which delays its absorption, so that the action is weak in the morning but prolonged to reinforce the protamine-zinc-insulin in the night or early morning; that, in fact, it acts as one of the "delay" insulins. I hope to procure some pre-war hoarded insulin to test this theory, but meanwhile perhaps your readers can throw further light. I shall be grateful if anyone can help me to obtain pre-war insulin.—I am, etc.,

G. M. WAUCHOPE, M.R.C.P.

SIR,—Dr. E. Sutherland-Rawlings (June 13, p. 739) has made the significant statement that most hypoglycaemic attacks occur in the early hours of the morning, and suggests that prophylactic measures should be taken to decrease their incidence. I would like to endorse this view. Insulin hypoglycaemia is an emergency state for which there is specific treatment. It is of common occurrence and usually harmless if prompt treatment is given. Delay in administering the treatment may have progressively serious results.

The protean manifestations of hypoglycaemia are well known, but in my experience the symptoms differ with the type of insulin used. Where soluble insulin is used, any sudden alteration in the blood-sugar level will produce a hypoglycaemic reaction, and a definite chain of symptoms characterizes the reaction. They can be ascribed to adrenaline secretion, and most commonly comprise shakiness, trembling, nervousness, emptiness, hunger, sweating, tachycardia, pounding pulses, and faintness. On the other hand, with Z.P.I. (zinc-protamine-insulin) there is usually an absence of those manifold manifestations which are attributed to the protective discharge of adrenaline. The reduction in blood sugar is so gradual that the suprarenal glands apparently are not aroused, and the secretion of adrenaline—a safety mechanism—is not called forth.

First effects are referable to cerebral disturbances. Drowsiness, nausea, and headache are observed, or, at first, there may be nothing more than a vague feeling of fatigue and malaise, which cannot be differentiated from fatigue from other causes. It is followed by increasing weakness and then by a little numbness about the mouth or at the ends of the limbs. Finally, the drowsiness increases, or, in some cases, euphoria develops, or delirium, or muscular incoordination, with twitchings of muscles, contortion of the face, or actual convulsions.

The fall in blood sugar is so slow with Z.P.I. that a much lower level of blood sugar has to be reached before any hypoglycaemic symptoms present themselves; the blood-sugar level may fall as low as 40 mg. per 100 c.cm. before symptoms of hypoglycaemia appear. The seriousness of the hypoglycaemic reactions arises from the fact that they are often insidious in onset, and the patient is liable to develop severe symptoms without warning. As the action of Z.P.I. extends for twenty-four hours, and as it takes longer to exert its maximum effect than soluble insulin, hypoglycaemic reactions are prone to occur during the night or sleeping hours, when the injection is given before breakfast, as is customary. In the early hours of the morning the insulin action is unopposed by the inflow of food. The important thing is, of course, to prevent these attacks from occurring, and this can be done by arrangement of the dietary carbohydrate. Since hypoglycaemic reactions are most likely to take place during the night, carbohydrate should be allowed before going to bed. Bedtime feeding is by far the most satisfactory method of preventing such reactions. A workable plan is to give one-sixth of the available carbohydrate at bedtime. This greater spreading out of the dietary carbohydrate is one of the advantages obtained with the use of Z.P.I. Indeed, the most striking feature, from the metabolic point of view, with Z.P.I. is the abolition of states of transient ketonaemia resulting from tissue breakdown. Even during the period of hyperglycaemia and glycosuria after a meal there is no recurrence of ketonuria as judged by the sensitive nitroprusside test.

The hypoglycaemic effect of exercise and muscular exertion raises important considerations in the use of insulin. Unusual exertion in diabetics on soluble insulin usually results in hypoglycaemia, but this is limited to the time of its maximum action, which can be foreseen and avoided. Z.P.I., however, with its prolonged action, makes unusual exercise apt to produce hypoglycaemia at almost any time of the day. There is no need to impose restrictions on the patient and order a "time-table existence" or carefully regulate the amount of exercise. Instead, extra carbohydrate should be given after the exertion, so that the depressing effect of the exercise on the blood sugar is neutralized. All unwonted exercise should be associated with an extra ration of carbohydrate.

As insulin is obtainable in different strengths it is very important for the patient to study the label on the rubber-capped phial to know just what he is using. Apart from using the wrong concentration of insulin per c.cm. (in the bottle) as compared to the scale on the insulin syringe, he should learn to avoid errors in filling the insulin syringe. Sometimes there is a misunderstanding about the amount of insulin prescribed. A unit is a unit, whatever the strength of insulin. That is to say, if 20 units of insulin are ordered the syringe must be filled to the 20-unit mark—using single-strength insulin. If double-strength insulin is used, the syringe must be filled to the 10-mark. And if quadruple-strength is used, the syringe must be filled to the 5-mark. In all these cases, whatever strength of insulin is used, 20 units are being given. It is, consequently, advisable to use a syringe marked in units, as it is more difficult, if not confusing, to work out the dosage using one marked in fractions of a c.cm.

There are three kinds of insulin that are available in this country: (1) Insulin hydrochloride in solution in weak acid, *p*H 3.4. Synonyms for this kind of insulin are: old insulin, unmodified insulin, clear insulin, regular insulin, ordinary insulin, quick-acting insulin, and soluble insulin. (2) Protamine-insulin, which is a suspension at neutral reaction, *p*H 7.2. Synonyms for this kind of insulin are: Hagedorn insulin, Leo "insulin retard," protamine insulinate, delay insulin, and Danish protamine-insulin. (3) Zinc-protamine-insulin, which is also a suspension at neutral reaction. Synonyms for this type of insulin are: protamine-zinc-insulin, Canadian protamine-insulin, and protamine-insulin (with zinc) suspension. The nomenclature of insulins needs clarification. Up till 1935 there was available only one kind of insulin; the word "insulin" meant only one thing. Since Hagedorn of Denmark introduced protamine-insulin and Scott of Toronto produced zinc-protamine-insulin there has been a lot of confusion, because of the multiplicity of names. To distinguish the old insulin from the other, more recently introduced insulins it is convenient to refer to old insulin as soluble insulin and the other as suspended insulins. Of the three types of insulin the preparations can be obtained in the following different concentrations: Soluble insulin—20 units per c.cm. (single strength); 40 units per c.cm. (double strength); 80 units per c.cm. (quadruple strength). Protamine-insulin—40 units per c.cm. (double strength); 80 units per c.cm. (quadruple strength). Zinc-protamine-insulin—40 units per c.cm. (double strength); 80 units per c.cm. (quadruple strength).—I am, etc.,

Guy's Hospital GEORGE R. W. N. LUNTZ.

Bacteriophage Treatment of Bacillary Dysentery

SIR,—With reference to the interesting paper by Dr. Arthur Compton (June 13, p. 719) giving comparative statistics of treatment in Egypt, may I point out that his figures deal only with death rates and do not, and in the circumstances cannot, give figures for the duration of illness. From the point of view of the medical branches of all three Services, whose aim is to return a fit patient to duty at the earliest possible moment, these figures are as important as the death rate.

Through the courtesy of Dr. Compton, Major Jameson, R.A.M.C., and I were able to try out the bacteriophage treatment of dysentery in a Service hospital during the autumn of 1940. The series was small, consisting of 12 cases with 8 controls which were treated with the then standard treatment of sodium sulphate and fluids. All patients recovered, as did the controls, but there was little variation in hospital time between the two groups, certainly not enough to justify the continuation of the bacteriophage treatment. The introduction of sulphaguanidine in the spring of 1941, which enabled us to reduce the duration of illness, even in some cases of *B. shiga* infection, to 11 days from the onset, even when the patient was not admitted before the third day, appeared to make the further trial of bacteriophage superfluous.

There are, of course, other points to consider: (1) Dr. Compton's figures deal with a whole community, whereas we were dealing with a limited age group (20–50), which, moreover, did not include women, children, or old persons, and none of our patients was suffering from other diseases. (2) Civilians in Alexandria are so "phage-minded" that to my knowledge they treat themselves with bacteriophage on the slightest suspicion of "Gyppy tummy," whereas in our cases treatment with bacteriophage was rarely begun before the second or third day. (3) Our cases were all "virgin soil," whereas, owing to the endemicity of bacillary dysentery in Alexandria, I should imagine that the local inhabitants must all possess a partial immunity with its concomitant titre of dysenteric bacteriophage, which is greatly increased by treatment with this substance. (4) We had no opportunity of trying out the prophylactic value of bacteriophage, to which, I know, Dr. Compton attaches importance.—I am, etc.,

D. C. WILSON,
Surgeon Commander, R N V R.

Active Rehabilitation in the R.A.F.

SIR,—Those Fellows of the Royal Society of Medicine who were present at a recent meeting at an R.A.F. hospital, I am sure, could not fail to have enthused over the technique and film of rehabilitation of fracture patients. We were shown how patients who were confined to bed with a fractured limb were given hourly exercises to tone up not only the muscles of the injured limb in plaster or splints, but also those of the trunk and other free limbs. Thus once the period of recumbency is over the patient is able to take part in active rehabilitation team-work or games. A film was shown in which men with legs in plaster took part in cycle team-work and played games such as football, etc. All were under the supervision of a massage orderly or medical officer.

How different from our feeble efforts still in most civilian hospitals, where a patient in plaster lies and physically rots in bed, or loafs about on a stick in ward or corridor, where the best effort a masseuse of the C.S M.M.G. can do is her routine stock-in-trade of massage or faradism to the injured limb. Surely the wonderful effort made in the R.A.F. medical team must produce magnificent results—a man going back to his job with zest, rather than the half-hearted way the workman who has had a fractured limb, labouring under the worry of litigation under the Workmen's Compensation Act, is cajoled back to his normal self.

Surely the time has come for the Chartered Society to take up the new spirit in training its members, and to run a refresher course in modern rehabilitation methods at which some of these R.A.F. methods and results could be preached by Mr. Watson-Jones. Nor did I fail to note that the medical officer himself, putting dignity to the wind, showed his patient how co-ordination and normal gait should be attained in walking or skipping: rather different from just going round a ward in a white coat giving instructions to a masseuse or sister. I am aware that these are not new methods to such pioneers as Mr. H. E. Griffiths at the Albert Dock Hospital or Mr. E. A. Nicoll at Mansfield, but in the words of the final caption on the R.A.F. rehabilitation film, some of us surgeons dealing with fractures with our masseuses must 'Go to it."—I am, etc.,

London, N W 1. G. O. TIPPETT, F.R.C.S.

Mental Symptoms in Bromide Intoxication

SIR,—Dr. Howard Kitching's interesting article (June 20, p. 754) prompts me to describe briefly 2 cases which occurred in my practice some years ago.

1. Man aged about 50. Symptoms of effort angina. Small doses of sodium bromide were administered over a period of 2 or 3 months. A consultant considerably increased the dosage. Three days later a policeman rang my night bell and informed me that he had found one of my patients wandering in the road in an almost nude condition. I hastened to the patient's flat and found him restless, agitated, and tremulous. He appeared hallucinated and did not recognize me. The question of certification arose and the climax came with refusal to take medicine. I was surprised to note the gradual disappearance of mental symptoms.

2. Lady aged over 70, suffered from arteriosclerosis and hyperpiesis. Bromide had been given for some weeks. On one of my periodical visits I found her incoherent, confused, and depressed. Her speech was slurred. Slight cerebral haemorrhage appeared to have supervened. Medicine was discontinued. At the end of a week the patient was bright, cheerful, and speech was normal.

Dr. Howard Kitching's reference to the number of N.H.I. prescriptions containing bromide (Barbour, Pilkington, and Sargant, 1936) is of special interest. It seems possible that many cases of mild intoxication are overlooked. My experience of skin lesions is that they are more likely to occur when initial dosage is comparatively large.—I am, etc,

Nottingham. J. J. GIBB.

Operations and Workmen's Compensation

SIR,—Your article on the legal aspect of operations as they relate to injured workers and workmen's compensation (June 20, p. 776) is most instructive; moreover, it is gratifying to see that you recommend a broader vision in this matter taking into account the psychological and sociological attitude of the worker. There can be no doubt that the worker's mental attitude towards the workmen's compensation law as it now stands is a very unfavourable one. So long as he remains under the impression that doctors employed by insurance offices are biased in favour of getting him back at any price to some sort of light work, and to achieve thereby payment of compensation for partial incapacity, his reluctance to undergo operations, for good or evil, will remain.

It is deplorable that the matter leads to dispute between the doctor of the insurer and the worker's doctor. There are reasons enough to make the latter reluctant to accept the opinion of his opponent. Will the effect of the operation be of lasting value? Will the worker after operation really find the desirable "light work"? What will be his position if, after being put on light work with compensation for partial incapacity, a second accident occurs, perhaps resulting from his disability, and the process of litigation begins all over again? What will be the worker's position if, after the operation, he needs appliances, costly to procure and costly to repair and maintain, while there is no statutory provision under either the National Health Insurance or Workmen's Compensation Acts for their supply?

The danger that "professional medical witnesses," highly skilled in presenting a particular aspect of the case, may exercise much influence on a lay court, to use Dr. W. A. Brend's apt observation (*Traumatic Mental Disorders in Courts of Law*, 1938, p. 93), cannot be denied, and the demand for medical boards which, as Dr. Brend puts it, "would tend to select their expert witnesses and advisers more for professional status and integrity than for their skill in masked advocacy" appears to be fully justified. The whole problem is another proof of the need for redrafting as soon as possible industrial accident insurance in this country. Indeed the unsatisfactory conditions relating to operations under the present workmen's compensation law illustrate once more that the latter tends to prolong invalidism, a matter which has been recently discussed on a broad background and with much vigour before the Royal Society of Medicine by such authorities as Dr. Bernard Hart and Mr. H. E. Griffiths, from the medical point of view, and by His Honour Tom Eastham, K.C., from the legal.—I am, etc.,

HERMANN LEVY.

Adrenaline Bronchoconstriction

SIR,—The chief action of adrenaline is to produce vasoconstriction, and those who maintain that asthma is the result of muscular bronchospasm find difficulty in explaining how an injection of adrenaline stops an asthmatic attack, because its action on muscular fibre is very slight, beyond reducing blood supply. When an injection of adrenaline is given it produces a systemic vasoconstriction and the blood pressure rises, but this is quickly followed by a reactionary vasodilatation, when it will be found that the blood pressure falls below its original level, and it is then that the relief of dyspnoea is experienced. This systemic vasodilatation relieves the local vasodilatation of the bronchial mucosa, which had previously been maintained as compensatory to the systemic vasoconstriction and was the cause of the dyspnoea. Repeated large doses of adrenaline are apt to interfere with, or prevent altogether, the subsequent vasodilatation reaction, and so relief of the dyspnoea is not obtained; in fact the condition may be made worse by continuing the adrenaline injections. When this state has been reached it will be found that a single injection of morphine will usually give immediate relief, after which, not infrequently, no further adrenaline is needed, and in any case a smaller dose will then be found effective.

All this difficulty arises from the inherited traditional belief—one of the hardest things in medicine to overcome—that asthma is the result of muscular bronchospasm, and this makes it necessary, in order to explain how adrenaline relieves an asthmatic attack, to pervert its natural action on the vasomotor system, and make it act, for this occasion only, as a muscular dilator.—I am, etc.,

London, W 1. ALEXANDER FRANCIS.

Respirator Dermatitis

SIR,—J. Petro (May 23, p. 631) has well described and illustrated his careful investigation of contact dermatitis caused by rubber respirators. In therapy his mainstay was calamine lotion. Because the irritant is usually a reducing agent, I believe he would get better results from the use of an oxidizing medicament, such as 1 in 3,000 potassium permanganate solution in cool moist compresses frequently refreshed, or sodium perborate 5% to 10% in a greaseless ointment base or hydrous wool fat.

The anti-oxidant of rubber can often be neutralized, as Obermayer pointed out (*Arch. Derm. Syph.*, Chicago, Jan., 1933, **27**, 25), by soaking the rubber appliance overnight in 4% sodium hydroxide in water. The appliance must then be rinsed thoroughly before use, and after hydroxide treatment it may prove innocuous. The "dry, scaly stage," which Petro described as being resistant to treatment, may represent complication of dermatitis venenata by seborrhoeic dermatitis extending from the scalp. I have noted such complication (*Synopsis of Diseases of the Skin*, The C. V. Mosby Company, St. Louis, 1942, p. 82), and I recommend for it the use of 2% crude coal tar in lanoline, to which water is added to make the salve creamy. The scalp must be treated simultaneously. Washing should be done with a sulphonated oil rather than soap. I hope that this criticism is constructive and useful.—I am, etc.,

Kansas City, U S A. RICHARD L. SUTTON, jun., M.D.

Doctors as Politicians and Strategists

SIR,—I am a member of the Socialist Medical Association but was not present at the meeting to which your annotation refers, and do not think I should have voted for the resolution there stigmatized, because I do not know the precise connotation of the phrase "second front"; arithmetically there seem to be at least four "fronts" at the present time if a "front" is a locus where gallant men are fighting and dying in large numbers. But I suggest that your contributor should descend from the pantomime elephant on which he is perched and choose a more lowly quadruped, say, a donkey. Had the S.M.A. passed a resolution to the effect that, on *medical* grounds, the "formation of a second front" was desirable, it *would* have deserved ridicule. But the fact, quite as obvious to the derided man in the street as to your contributor, that members of the S.M.A. have no more knowledge of strategy than any other sample of educated men and women, acquits them of any charge of seeking to exercise an illegitimate influence on public opinion. Why a society of medical men and women should have less liberty to express an opinion on matters of general interest than any other incorporation of the King's subjects is not obvious. A much greater danger to the prestige of our profession is when medical individuals or societies express dogmatic opinions on subjects which are, or may be thought to be, within the scope of their expert knowledge but have in fact never been seriously studied by them. Examples of this fault are sufficiently numerous.—I am, etc.,

Loughton. MAJOR GREENWOOD.

SIR,—Your annotation (July 4, p. 16), apart from giving publicity to the Socialist Medical Association, elaborates the well-worn text that the doctor must stick to his last and not dabble in politics.

You state that "the grim realists who are courageously directing Russian policy must feel mildly amused at the picture of the English doctor turned strategist." May I refute that statement with the words of Georgi Miteryev, People's Commissar of Public Health in the U.S.S.R., who in a message last week to Sir Alfred Webb-Johnson, which was read at a meeting of the Anglo-Soviet Medical Council on June 29, said: "We highly appreciate the help rendered us by the scientists of England and the entire people of the British Empire in our common struggle against the enemy of all progressive mankind, and are confident that the opening of a second front in Europe in 1942 will bring closer the day on which peoples of our countries together with all the freedom-loving peoples of the world will celebrate a final victory over bloodthirsty Hitlerism." Judging by results, Stalin (who doubtless should have stuck to his last in the theological seminary where he received his early training) and the Soviet people know what they are talking about.

Since the early establishment of a second front in Europe is the declared policy of our Government, I suggest, Sir, that the Prime Minister, who has already discussed this question with the Soviet Foreign Minister, should be left in no doubt as to the support this country will give him in carrying out this essential step towards a speedy victory. Why, therefore, is it "slightly ridiculous" for a body of socialist medical workers to express their support of this policy at the present time?—I am, etc.,

London, S.W.17. L. T. HILLIARD, M.B.

SIR,—I desire to protest against your annotation "Doctors as Politicians and Strategists." I consider that this article is neither courteous nor well reasoned. It is the privilege of every adult British citizen to vote on political issues, and it is his duty to render himself competent to vote by a careful study of politics. The successive crises of Manchukuo, Spain, and Czechoslovakia have demonstrated the intimate connexion between policy and strategy. The "grim-realists" who are directing Russian policy were the first to emphasize the importance of universal political education, and they would hardly excuse members of a learned profession who confessed themselves too preoccupied to study urgent political questions. I should be very sorry if your annotation were allowed to pass without protest from at least one member of the B.M.A.—I am, etc.,

London, W.C. O. F. H. ATKEY.

SIR,—The activities of the Socialist Medical Association mentioned in your columns give rise to several interesting questions. To begin with, the formation of a Socialist Medical Association implies that there is such a thing as socialist medicine? What is socialist medicine? Do members of the Socialist Medical Association claim to practise a peculiar kind of medicine which is unknown to, or not understood by, their non-socialist colleagues? Or do socialist patients differ so much from the ordinary run of humanity that they can only obtain efficient medical treatment from socialist doctors? Or is it just a political stunt?—I am, etc.,

Epsom. A. J. COLBY-TINGEY.

SIR,—The writer of your annotation takes considerable exception to a recent resolution passed at the annual general meeting of the Socialist Medical Association, in which our support for the opening of a second front in Europe in 1942 was expressed. Perhaps your writer is unaware that this is the official policy of our Government and of the United Nations. May I refer him to a statement issued by the Foreign Office on June 11, on the treaty between the Soviet Union and our own country, in which these words occur: "Full understanding was reached between the two parties with regard to the urgent tasks of creating a second front in Europe in 1942." One is driven to conclude that there are only two possible explanations of your writer's warmth of disapproval of the S.M.A. resolution, the first being that he has taken this opportunity of disagreeing with the expressed policy of the United Nations. We hesitate to think that you would be willing to give space to a writer with such aims, and are therefore left with the second explanation—that in him parochialism has grown to such an extent that he has forgotten that a doctor is not only a doctor but is also a citizen, with the full duties and privileges of citizenship.

Your writer says, "One would have thought that medical men had enough to do now . . . in matters concerning the organization of their profession," but he completely ignores the fact that the S.M.A. memorandum from which he takes his quotations goes on to outline proposals for immediate steps which we consider should be taken in order that the medical services may the more efficiently meet the demands which will undoubtedly be made on them when the second front is opened. We would remind him that the plans now being made for the reorganization of the profession *after the war* will have no chance of being put into effect unless the medical profession considers how to achieve the utmost degree of efficiency in the prosecution of the war *now*. No one reading this annotation would realize that the S.M.A. resolution was the preamble to a series of proposals for increasing efficiency. Your writer, like the rest of us, is entitled to hold his own opinions and to express them. He is not entitled to misrepresent the facts.—I am, etc.,

ALECK W. BOURNE,
Hon. Secretary, Socialist Medical Association.

*** Space will not allow this interesting correspondence to be continued. Needless to say, both of Mr. Aleck Bourne's "possible explanations" are entirely wide of the mark.—ED., *B.M.J.*

Analytical Chemists and E.M.S. Laboratories

SIR,—I am grateful to Dr. Griffith Evans, president of the North Wales Branch of the British Medical Association, for his letter (June 20, p. 774) directing attention to the serious injustice done to public analysts and other analytical chemists in various parts of the country through the operation of the Emergency Public Health Laboratory Service.

The Institute of Chemistry has been in correspondence with the Ministry of Health on this matter since November, 1939, but although the Ministry may appreciate that public analysts and other analytical chemists play, and have for a long time played, a most important role in the preservation of the health of the community throughout this country by the examination of food, water, milk, etc., it has apparently overlooked the fact that the maintenance of the laboratories in which this work is done may be seriously jeopardized if the analysts are deprived of any large section of their professional practices by unfair competition.

Analytical and consulting chemists, like medical men, both individually and as members of a professional body, strongly uphold the tenet of professional procedure which forbids soliciting for practice; yet circular letters have been addressed to medical officers of health and other medical practitioners offering the services of emergency public health laboratories and soliciting in such terms as, "Hoping that we may be of assistance to you in the future." Your readers may well imagine the feelings of medical men if attempts were made to interfere in this way with their professional practices.

The correspondence between the Institute and the Ministry has been somewhat protracted and has not yet been concluded, but it is encouraging to find a supporter in the medical profession who appreciates not only the impropriety of the proceedings referred to, but the extreme danger of transferring work of the character indicated from persons of long experience in a particular district to others comparatively recently qualified.—I am, etc.,

RICHARD B. PILCHER,
Russell Square, W.C.1. Registrar and Secretary, Institute of Chemistry.

SIR,—It was most refreshing to read the letter from Dr. Griffith Evans with reference to stranded public analysts, and to find that the pledge given in 1939 by Sir Arthur MacNalty had not faded from the memory of everyone. There can be little doubt that it is no more than a memory, however, as it has never been possible to persuade any of the authorities to implement it, or any other member of the B.M.A. than Dr. Evans to support it.

It might, perhaps, be not amiss to remind Dr. Evans that charity begins at home, and that while defending members of other professions he might do well to note that his words apply verbatim to the unfortunate pathologists who have been stranded by the "new order" in pathology. Many of these have offered themselves with their laboratories, equipment, and staff to this "new order," and their offers have been not merely refused but ignored. These methods of "liquidating" the existing members of a profession seems to savour of the very principles against which this war is being waged. Those who venture to protest are reminded that a national emergency exists. Surely such an emergency is just the time when the help of these unfortunate individuals is most needed, and it is now clear that the emergency service is to be used as a Trojan horse of the woodenest kind to ensnare the profession after the war is over.—I am, etc.,

PATHOLOGIST.

Nurses in Hospital

SIR,—The brutality of matrons (and sometimes of sisters) to their nurses is notorious. It needs no investigation. (It is not universal. I know one hospital well in which the nurses, and particularly the probationers, are watched over with an almost maternal care.) Why does this state of affairs exist and why is it allowed to continue?

I think it is because: (1) the care of the nurses is left entirely to the matrons; and (2) the matrons are chosen for their organizing and disciplinary capacity without regard to their humanity. The fact that matrons, as a class, are conscientious workers, devoted to duty, only makes matters worse. They have been through the mill and have survived. They are healthy and hard and they think others should be the same. An occasional slacker or would-be valetudinarian among the nurses confirms the matrons in their mercilessness.

The remedy lies with hospital boards and medical officers. Matrons must be made to realize that they are responsible for the health and comfort as well as for the efficiency of their staffs. To this end there must be propaganda. The Ministry of Health and the nursing press are obvious means. Perhaps two or three actions against hospitals for compensation in carefully selected cases in which life or health has been needlessly sacrificed might help. Have the nurses an organization that could carry this out?

The feeding of nurses and their opportunities for relaxation are, on the whole, much better than they were, but there is still room for immense improvement in some hospitals.—I am, etc.,

Colwyn Bay. S. L. B. WILKS.

Obituary

JOHN CHARLES DAVIES, M.D.

Many members of the B.M.A. will learn with regret of the death of Dr. J. C. Davies, J.P., which took place at his home at Rhos, near Wrexham, on June 24. He had been president of the North Wales Branch and chairman of the Denbigh and Flint Division, and served on the Welsh Committee for six years, on the Insurance Acts Committee for twelve years, and on the Rural Practice Subcommittee for thirteen years.

John Charles Davies was born at Pant in May, 1859, and after studying medicine at the London Hospital qualified M.R.C.S., L.S.A. in 1882, took the L.R.C.P. in 1884, the D.P.H. in 1899, and the M.D. of Durham University in 1901. During sixty years of practice at Rhos he won the love and esteem of all the neighbourhood. He held many local appointments and was consulting surgeon for the North Wales district of the Great Western Railway and surgeon to the Ruabon Accident Hospital. To the end of his days Dr. Davies kept abreast with new discoveries and movements in the world of medicine and surgery, and made many journeys to attend medical functions and conferences. When in London he rarely missed the chance of a visit to the Royal College of Surgeons, and right up to the outbreak of the present war he annually went for fourteen days to some postgraduate course. He was heart and soul for B.M.A. work, and apart from that his chief hobby was the permanent mounting of pathological specimens from cases under the care of his son, Dr. A. Lloyd Davies, in the War Memorial Hospital at Wrexham.

Dr. Davies was instrumental in forming the first Territorial company in Rhos, of which he was captain. In November, 1914, he led his company to France, and after enduring many hardships of war he was transferred to the R.A.M.C., where he worked in field ambulances and other forward units in France and Flanders, and retired from the Army with the rank of lieut.-colonel. On returning to civil life he continued in active practice, and was attending patients until three weeks before his death at the age of 83. In 1928 Dr. and Mrs. Davies received a public testimonial from the people of Rhos in recognition of his great and beneficent services. Of no one can it be more truly said that he lived for his profession and his patients.

C. W. PAGET MOFFATT, M.B., D.P.H.

Dr. Christopher William Paget Moffatt, late M.O.H. for Bolton, one of the most prominent members of the Public Health Service, died on May 18, aged 79, in Southport, where he had lived in retirement for some years.

Paget Moffatt received his early education in Brussels, where his father was British chaplain for the Colonial and Continental Church Society. He afterwards studied in the Universities of London, Göttingen, Cambridge, and Liverpool. Before entering medicine he studied modern languages and obtained the M.A.Lond., being placed at the head of the list in both French and German. He was at this time well known as a teacher of languages, and was for some years on the staff of the University Correspondence College. He was the author of two textbooks, *Science French* and *Science German*, still used with unfailing success for the purpose for which they were originally intended. Paget Moffatt later began the study of medicine at Cambridge, where he graduated B.A. (Nat. Sciences

Tripos), afterwards taking the Conjoint diplomas, the M.B. (Kanthack gold medal in pathology) and B.Ch.Camb. in 1904, and the D.P.H. 1905. His thesis for the M.B., on myelopathic albumosuria, was published in the *Lancet*. He took his clinical course at Liverpool, where after qualification he held the appointments of medical officer to the Northern Dispensary, hon. anaesthetist to the Royal Southern Hospital, and clinical assistant to the throat and ear department at the Royal Infirmary.

Deciding to enter the public services, he accepted an appointment as assistant M.O.H. and assistant school medical officer to the Bolton County Borough in 1908. In 1914 he was appointed deputy M.O.H. and tuberculosis officer, which positions he held until 1921, when, on the retirement of Dr. Gould, he was appointed medical officer of health and school medical officer. He also acted as medical superintendent of the borough isolation hospital from 1914 to 1931, and from 1922 to 1931 was senior medical officer to the venereal diseases department. From all these positions Dr. Paget Moffatt retired in 1931. After leaving Bolton he was engaged for two years as temporary M.O.H. for a combined district at Epsom pending the alteration of certain areas under a scheme of the Surrey County Council. He was a member of the British Medical Association, and of the Society of Medical Officers of Health, of the North-Western Branch of which he was president in 1926-7.

Paget Moffatt (writes a former colleague) was a man of outstanding personality. He brought to his public health duties a thorough training in medicine, together with a wide and accurate scholarship. During the whole period of his administrative appointment he maintained an active interest in the various hospitals and clinics under his control, particularly the infectious diseases hospital; for clinical medicine was his real interest. He loved attending patients and they loved him. He never allowed the doctor to be submerged into the official. It was difficult to think how he found time for his many activities, but he was a rapid worker. He was never irrelevant. His long experience enabled him to grasp and solve problems very quickly and to translate his decisions into prompt action. He was an excellent companion, there being no dull moments in time spent with him. He will long be missed by those who had the privilege of his friendship.

Dr. **ALEXANDER BRYCE**, who died on June 7 in his 80th year, had been a member of the B.M.A. since 1888 and was honorary secretary of the Section of Therapeutics when the Association met at Birmingham in 1911. He studied medicine at the University of Glasgow, graduating M.B., C.M. with first-class honours in 1886, and M.D. with honours in 1893. As a student he won the Brunton memorial prize, and after qualification was assistant to the professor of medical jurisprudence at Anderson College and took the D.P.H. of Cambridge. It was Lawson Tait, the eminent surgeon, who persuaded Bryce to start a practice in Birmingham. The two met on a golfing holiday. Bryce, having completed his brilliant career at Glasgow University, had begun to practise in Killin; he was there for just three years. He went to Birmingham in 1894 and quickly took his place in rank with the galaxy of medical men then busy in Birmingham—Tait, Gilbert Barling, Stacey Wilson, Thomas Chavasse, James Sawyer, and Jordan Lloyd. Some of his friends urged him to specialize in surgery, but Bryce preferred to go ahead as a general practitioner and to specialize only in branches that particularly appealed to him: dietetics and manipulative surgery. He quickly built up a considerable practice, and was associated with Robert Jones in orthopaedic work. In 1899, to further his knowledge of the American approach to dietetics and to manipulative treatment, Bryce visited the United States, and when he came home he gave himself more and more to the study of these subjects. His book *The Laws of Life and Health*, designed for popular instruction, went through several editions and was reissued in revised form shortly before the outbreak of war. In 1923 he took up an appointment as chief medical officer for the Britannic Assurance Company and retained it until he retired in 1939.

We regret to announce the death at Oxford on June 29 of Dr. **WILLIAM DUNCAN STURROCK**, assistant obstetric physician to the Radcliffe Infirmary, and since 1927 medical officer to Radley College. He was born on May 16, 1880, and from Charterhouse went up to Magdalen College, where he gained a first class in the Final Honour Schools in Physiology, and then went on for his clinical studies to King's College Hospital, graduating B.M., B.Ch. in 1906. After holding house appointments at King's and at the Royal Free Hospital he began practice at Oxford in 1908, and took his D.M. in 1912. He served throughout the last war in Flanders and Macedonia, reaching the rank of lieut.-colonel in command of the 82nd Field Ambulance, and after the Armistice was posted to Transcaucasia. He was twice mentioned in dispatches and awarded the D.S.O. in 1918. He joined the B.M.A. in 1908, and was vice-president of the Section of Obstetrics and Gynaecology at the Oxford Meeting of the Association six years ago. He had also been president of the Oxford Medical Society. Sturrock was a keen golfer and fisherman, and his son's performance as an outstanding member of the Oxford crew gave him obvious pleasure.

By the recent death at the age of 84 of Dr. **HERBERT RYDING MOSSE** of Aldwick, near Bognor Regis, formerly of Horsham, the two principal medical charities have lost a generous friend of a type that they can ill spare, for he had subscribed annually to both the Royal Medical Benevolent Fund and the Royal Medical Foundation of Epsom College for many years, and the total of these benefactions fell little, if at all, short of £600. In addition, he handed to Epsom College in 1928 stock then valued at £1,000—worth a good deal more now—to found a leaving exhibition, tenable for one year only, by a boy entering on some definite career. Dr. Mosse studied at Charing Cross Hospital Medical School, whence he became M.R.C.S., L.S.A. in 1882, and M.D.Durh. in 1885. He was house-surgeon at Charing Cross Hospital, R.M.O. at the Bolingbroke Hospital, Wandsworth, and M.O. to the Wandsworth Provident Dispensary. He was a keen archaeologist and historian, and the author of books on various aspects of Sussex history and prehistory. He was a Fellow of the Royal Horticultural Society, and a member of various other learned bodies.

Dr. **ERIC J. WHYMARK** died on June 4 at the early age of 43 years, after a short illness. He was educated at the Liverpool Collegiate High School and at Liverpool University, taking the M.B., Ch.B. degrees in 1923. After qualifying he held appointments as house-surgeon at the David Lewis Northern Hospital, and medical officer to the Brownlow Hill Institution, Liverpool. At the time of his death he had been in general practice for fourteen years, and had specialized in anaesthetics, holding appointments of honorary anaesthetist at the Liverpool Royal Infirmary and anaesthetist at the Walton Institution. Up to two years ago he was honorary anaesthetist at the Women's Hospital. During the latter months of the last war he served in France as second lieutenant with the 9th Batt. of the King's Liverpool Regiment. Dr. Whymark took an enthusiastic interest in anaesthesia, being a valued member of the committee of the Liverpool Society of Anaesthetists, and his colleagues greatly mourn his loss. Whether in anaesthetic work or private practice his one thought was for the welfare of his patients, and he was held in high esteem by all.

Universities and Colleges

UNIVERSITY OF BIRMINGHAM

At a Congregation on July 4 the following degrees were conferred:

HON. LL.D.—Arthur Stanley Barnes, M D, D Sc., F R.C.P, Dean of the Faculty of Medicine, University of Birmingham

M.D.—G. S. Hall.

M B, CH.B—*‡‖W. H. Bond, *‡¶J. C. Fulford, †A. W. Blackwell, †B. T. Davis, †G. M Holme, †Elizabeth A. Johnson, J. W. Abbiss, Margaret R. D. Banks, Winifred M Biddle, Jean S. I. Brown, G. B. Cliff, Margaret I. Coghill, Christine M. Edmonds, Margaret S. Garden, Lilian M. A George, J. T A. George, Elizabeth J. F. Heynemann, B. Hyde, D. H Joseph, ‡A. C. Kendall, J E. Kerton, Jean D MacArthur, D. McL. McDonald, Mary P. McHugh, D J S McIlveen, T. A Phillips, ‡M. C Platten, P F. Rudd, D. C. Sachdeva, P. R Sondhi, P. R Stephens, J MacF Stuart, H O Thomas, R. S. Thorpe, A Watson-Jones.

The following scholarships, medals, and prizes have been awarded:

Queen's Scholarship (fourth year), I. Macnab; (fifth year), R. W. Tudor; (final year), J. C Fulford. *Ingleby Scholarships*, W. H. Bond, J. C Fulford. *Foxwell Memorial Medal*, M. C. Platten. *Gamgee Memorial Medal*, W. H. Bond *Priestley Smith Prize in Ophthalmology*, G. M Holme. *Russell Memorial Prize*, Elizabeth A. Johnson. *Butterworth Prize*, J. C Fulford. *Leith-Newman Prizes in Pathology* (fourth year), Medical, Theresa Lazar; Dental, N. Norris. *Thompson Prize in Anatomy* (third year), R. H. Strudwick. *Windle Prize in Anatomy*, L. D. Abrams. *Humphreys Memorial Prize*, D. H Goose

* First-class honours † Second-class honours. ‡ Distinction in medicine, ‖ Distinction in surgery ¶ Distinction in midwifery.

UNIVERSITY OF BRISTOL

The following candidates have been approved at the examinations indicated:

FINAL M B., CH B.—[1][2]G. H Valentine, [1][3][4]G. H. Wattley, [5]Nancy R. Baldwin, R. F. Brooks, Rosalie M Child, D G Davies, J. Deighton, G F. McD Hall, Joyce Kennard, [4]A G H Mitchinson, E. W. Moore, J L. Pardoe, A R. Rowe, N. Slade, M H Thomas, Jean Wallace, G A. Walton, *In Group II (completing examination)*: K. L. Brown, A. H M Oakes

[1] Second-class honours. [2] Distinction in obstetrics. [3] Distinction in medicine. [4] Distinction in public health [5] Distinction in surgery.

Medical Notes in Parliament

Health in Scotland

In the House of Commons on July 8 Mr. Tom Johnston presented the health, housing, and education estimates for Scotland. He said there was evidence of improvement in the physical condition of school children despite the strains of war and, in some areas, an intensification of overcrowding. There was an increase in most respiratory diseases and in cerebrospinal meningitis, and a disturbingly high rate of infant mortality, but on the whole the public health was not deteriorating. Infant mortality per 1,000 births rose from 68 in 1939 to 78 in 1940 and 83 in 1941. He had asked the Department of Health's Scientific Advisory Committee under Sir John Boyd Orr to report quickly on the causes of this rise and to suggest remedial measures. The committee had co-opted a sub-committee of 12 experts on child health in Scotland. Meanwhile, infant mortality figures for 1942 showed, so far, a definite improvement.

With regard to infectious diseases the incidence of scarlet fever had fallen by one-half, and that of measles was also down; but there were increases in diphtheria, enteric fever, and whooping-cough. The number of diphtheria notifications, which averaged about 10,000 yearly before the war, rose in 1940 to 15,711; in 1941 there were 13,586, but for 1942 so far the number was again the pre-war average To-day 73% of school children and 58% of pre-school children in Scotland were immunized. Among the immunized children there was one death in about 1,000 cases; among the non-immunized there were 427 deaths out of about 7,000 cases. Referring to the outbreak of small-pox in Glasgow (*Journal*, July 11, p. 59), Mr. Johnston said that of 33 cases 20 had never been vaccinated and 13 had not been vaccinated since infancy. There had been 4 deaths. The City Medical Officer of Health and the Chief Medical Officer of the Department declared that the small-pox was of the most virulent and infectious type. The population of Glasgow had responded promptly to the appeal and 400,000 persons had gone voluntarily to be vaccinated. There was an adequate supply of lymph for all the population in the industrial area around Glasgow. Several medical officers of health reported that since the outbreak of war there had been a considerable increase in venereal disease, and the Scottish Office was considering whether further measures of control were possible. There was a disturbing increase in scabies; examination and treatment of verminous persons and the cleansing or destruction of verminous clothing were being carried out in a number of areas in Scotland. Cerebrospinal fever, a disease largely accelerated by wartime conditions, was still 5 times the pre-war figure, but in the first half of 1942 a considerable decline had been observed. Tuberculosis still showed an upward tendency, notifications for 1941 being 8,302, or over 800 cases more than in the last pre-war year. Mr Johnston here interposed the remark that the general health of Scotland would suffer greatly if next winter there was an acute shortage of domestic fuel. He spoke of plans for using timber-mill waste as a fuel reserve next winter.

Hospital Accommodation

Before the war Scotland was short of some 3,600 hospital beds; now it had, under Government ownership, 9 first-class acute hospitals with 8,000 beds, and 66 convalescent ones with 3,800 beds. So long as the beds were not filled with war service cases they should be used, together with the doctors and nurses who were standing by, to reduce the waiting-lists in the voluntary hospitals. Already nearly 6,000 of these waiting-list cases had been dealt with. An experiment in providing specialist diagnosis and treatment was being tried in the Clyde valley. Panel doctors' co-operation had been invited in this experiment, whereby any panel patient between the ages of 15 and 25 could be referred to the Regional Medical Service for specialist diagnosis and, where necessary, hospital and convalescent home treatment. These facilities were provided in the State hospitals and there was no charge. The scheme began in January, 1942, and by July 3 some 610 cases difficult to diagnose had been dealt with. In some cases the hospital doctors recommended that the Ministry of Labour should transfer the patient to more suitable employment. Mr Johnston said he hoped to see the system of specialist diagnosis and free treatment greatly extended, both in age groups and in areas. It already covered an area in which about 44% of the panel patients in Scotland resided.

Colonel Elliot asked for information about the supply of nurses for fever and tuberculosis hospitals, and Mr. Westwood (Under-Secretary of State for Scotland) replied that there was a definite shortage of nurses in all spheres of hospital work.

Colonel Elliot thought that if the gross number of beds and the gross number of nurses and reserved nurses in Scotland were taken they would find they had enough nurses. When the question of the E.M.S. was raised the Minister of Health and the Secretary of State for Scotland had said that girls would not be asked to serve in tuberculosis hospitals. He thought an invitation should be extended to see whether girls were willing to release the Government from that pledge and to serve anywhere. The rate for contracting tuberculosis in sanatoria was not, in general, as great as the rate for contracting it in ordinary hospitals, because greater attention was given to the subject. In time of war the nursing of tuberculosis was a form of service which they might not unreasonably ask the younger generation of women to accept.

Maternity Services

Replying to the debate, Mr. Westwood said he had been asked for details of the local authorities where doctors had refused to work under the schemes for maternity benefit. An arrangement had been made with the British Medical Association through its central body, but some local Branches of the Association refused to accept the terms. There was no scheme in operation in Argyll, but a meeting had been arranged with the doctors with a view to an agreement. All doctors in Dumbartonshire, except those in Helensburgh, had agreed to work the scheme. In Orkney meetings were being held with the doctors concerned. In Selkirk county the doctors had refused, but the matter was being taken up with the B.M.A. The scheme was not yet operating, but meetings with the doctors had been arranged in the burghs of Ayr, Dundee, and Kirkcaldy. In Clydebank burgh only two doctors had agreed to give their services. Dumfries county had a scheme which was not yet submitted, and in Dumfries burgh the scheme was not in operation. From the city of Edinburgh a scheme was submitted in draft. Glasgow had been allowed to postpone operation of the scheme until December, 1942. Mr. Westwood dealt with the provision of nurses, and said that a committee had been set up under Prof. T. M. Taylor, Aberdeen University, to draw up an agreed scale of salaries and emoluments for State-registered nurses employed in Scotland in hospitals and in the public health service, including the district nursing service, and for student nurses. The scope had been extended to cover midwives, health visitors, school nurses, and tuberculosis visitors. A grant to cover part of the cost of any increased expenditure on nurses' salaries was to be paid to hospital authorities. The Department awaited the report of that committee. There was a shortage of approximately 200 nurses for tuberculosis.

Call-up of Doctors' Staffs

On July 7 Sir Leonard Lyle asked the Minister of Labour whether, in view of the serious shortage of doctors for the civilian population, he would allow the maximum leniency with regard to the calling-up of their essential staffs, such as dispensing and surgical assistants and secretaries. Mr. Tomlinson, who replied, said that arrangements had already been made for safeguarding essential female staff employed by doctors. Qualified dispensers were not being withdrawn from their employment, and applications for the deferment or retention of secretaries and other assistants were considered individually in the light of their qualifications and the possibility of adequate substitution. Sir Leonard Lyle asked if a very serious situation was not already occurring with regard to the call-up of doctors, and if it would not grow worse, as was the case with the call-up of miners for the Forces. Mr. Tomlinson: It is precisely because of these circumstances that the procedure outlined is taken. Sir Francis Fremantle: Is there any appeal from a decision given against the deferment of the secretaries? Mr. Tomlinson: No, not in the ordinary way, but there is always an appeal to the Minister himself in the event of an obvious mistake having been made.

Analgesics given by Midwives.—In reply on June 11 to Dr. Summerskill, Mr. Brown reported that out of 188 local supervising authorities in England and Wales, 61 had made arrangements, before December 31, 1941, for the instruction of their midwives in the administration of analgesics at childbirth He would consider the issue of a circular to the other authorities urging like action. Sir Francis Fremantle asked Mr. Brown, if such instruction were not part of the regular training of midwives, to see that it was introduced.

Compensation for Nystagmus.—On June 16 Major Lloyd George informed Sir Francis Fremantle that in 1933 9,603 miners were in receipt of compensation for nystagmus, including 1,535 new cases and 8,068 cases continued from previous years. In 1938 the new cases numbered 1,019 and the continued cases 4,183, making a total of 5,202. Figures for the war years were not available

Deaths from Cancer and Diabetes.—On June 23 Mr. Ernest Brown informed Mr. Leach that the numbers of deaths in England and Wales from cancer and diabetes in 1940 were: cancer, 68,922; diabetes, 5,352. The figures for 1941, which were provisional, were: cancer, 69,228; diabetes, 4,865

The Services

CASUALTIES IN THE MEDICAL SERVICES

Acting Major **JOHN EWART EDSON**, R.A.M.C., died on June 10. He was educated at the University of Sheffield and King's College Hospital and graduated B.Sc. (with first-class honours in physiology) in 1929, proceeding M.Sc. in 1930, M.B., Ch.B. (with honours) in 1931, and M.D. in 1940. He was also admitted M.R.C.P.Lond. in 1936. He had held house posts at Sheffield Royal Hospital, and in 1935 was appointed assistant medical officer to the Mayday Hospital, Thornton Heath, Surrey, later becoming the senior assistant medical officer of the hospital. He entered the R.A.M.C. as temp. lieut. in May, 1940, and was promoted capt. a year later. He was a member of the B.M.A.

EPIDEMIOLOGICAL NOTES

Discussion of Table

In *England and Wales*, with the exception of measles, of which there were 244 fewer cases than in the preceding week, there was a general rise in the notifications of infectious diseases. The largest increases were those of dysentery, acute pneumonia, and diphtheria, with 80, 62, and 59 more cases than in the previous week, the two latter diseases being evenly distributed throughout the country.

Although the figure for whooping-cough was only 5 in excess of that for the preceding week, individual counties displayed considerable fluctuations. Rises were recorded in Yorks West Riding, Lancashire, and Kent of, respectively, 35, 30, and 24, and a fall of 81 was reported in Hertfordshire.

The heaviest falls in the incidence of measles occurred in Middlesex 129, Hampshire 63, Surrey 57, and Hertfordshire 54, but, in contrast to the general trend, rises were reported from Kent and Nottinghamshire, of 94 and 75.

The increase of 80 cases of dysentery was the biggest difference between two consecutive weeks since last August. Fresh outbreaks occurred in Cumberland 38 cases (Penrith U.D. 31, Ennerdale R.D. 7) and Denbighshire 20 cases (Colwyn Bay M.B. 11, Ruthin R.D. 6, Wrexham R.D. 3). In Yorks West Riding 28 cases were recorded (16 from the outbreak in Wortley R.D., and the remainder distributed through five areas): 13 cases from five administrative areas were recorded in Lancashire.

In *Scotland* the notifications of measles were 253 fewer than in the preceding week, Glasgow having 477, a fall of 223.

Small-pox

Six deaths from the outbreak in Glasgow have been recorded up to July 10. A vigorous campaign for vaccination has been carried out and over 400,000 of the inhabitants have been vaccinated. The cost of the outbreak has been estimated at £30,000. In Swindon the local authorities have made chicken-pox a notifiable disease, and over 18,000 people have been vaccinated.

Returns for the Week Ending July 4

The notifications of infectious diseases during the week in England and Wales included: scarlet fever 1,396, whooping-cough 1,457, diphtheria 728, measles 7,581, acute pneumonia 734, cerebrospinal fever 105, dysentery 242, paratyphoid 14, typhoid 4.

Vital Statistics of New York

The New York Tuberculosis and Health Association, with the co-operation of the various United States Bureaux, has issued a handbook containing the recent statistics of New York and the five boroughs of the city. The birth rate in New York, which had been declining (it was halved between 1915 and 1936), has during the last five years shown a tendency to a slight increase, and the rate of 14.4 per 1,000 of the population recorded in 1940 was the highest rate since 1933. The infant mortality was 33.3 per 1,000 live births for the white population and 54.7 for the coloured. The general death rate for 1940 was 10.2 per 1,000, 0.2 above the value for 1938, which was the lowest death rate ever recorded. The principal causes of death were heart disease and cancer, which accounted for one-third and one-sixth respectively of the total deaths.

The report consists of 17 tables and 14 diagrams, without any text at all. In the foreword it is stated: "Comparative death rates have been computed bringing out areas of the city where special attention is needed." This is hardly the case, as no attempt has been made at standardization for age or sex distribution; the rates are all crude rates. The diagrams, although of artistic merit, are not informative and are often confusing. The tabulation of leading causes of death by rank is unwieldy and makes it very difficult to follow the trend of mortality by age: in one table this method resulted in 18 lists of 10 causes of death.

No. 25

INFECTIOUS DISEASES AND VITAL STATISTICS

We print below a summary of Infectious Diseases and Vital Statistics in the British Isles during the week ended June 27.

Figures of Principal Notifiable Diseases for the week and those for the corresponding week last year, for: (a) England and Wales (London included). (b) London (administrative county). (c) Scotland. (d) Eire. (e) Northern Ireland.

Figures of Births and Deaths, and of Deaths recorded under each infectious disease, are for: (a) The 126 great towns in England and Wales (including London). (b) London (administrative county). (c) The 16 principal towns in Scotland. (d) The 13 principal towns in Eire. (e) The 10 principal towns in Northern Ireland.

A dash — denotes no cases; a blank space denotes disease not notifiable or no return available.

Disease	1942					1941 (Corresponding Week)

Rate per 1,000 total births (including stillborn)			34					28		

* Includes primary form for England and Wales, London (administrative county), and Northern Ireland.

† Owing to evacuation schemes and other movements of population, birth and death rates for Northern Ireland are no longer available.

Medical News

A whole-day conference under the joint auspices of the Nutrition Society and Food Group (Society of Chemical Industry) will be held at British Medical Association House, Tavistock Square, London, W.C., on Saturday, July 25, beginning at 11 a.m. The subject for discussion will be "Dehydration of Foods and the Effect on their Nutritional Value." The following speakers will take part: Dr. Franklin Kidd on the Principles and Practice of Food Dehydration; Dr. E. M. Cruickshank, Dr. J. G. Sharp, and Dr. E C. Bate-Smith, on Meat and Eggs; Dr. G A. Reay, on Fish; Dr R. J. L Allen, Dr. J. Barker, and Dr. L. W. Mapson, on Vegetables; and Sir Joseph Barcroft, on the Utilization of Dehydrated Foods. It is proposed to hold a conference on "Trace Elements in Nutrition," probably towards the end of October Further particulars can be had from the Hon Sec., Dr. Leslie Harris, Nutritional Laboratory, Milton Road, Cambridge. The Scottish Group of the Nutrition Society is planning the third conference in the series on "Food Supplies in Relation to Human Needs"—namely, "Signs and Symptoms of Deficiency Diseases" This will probably be held in August or September. Further information may be obtained from the Secretary of the Scottish Group (Mr. J. S. Thomson, Rowett Research Institute, Bucksburn, Aberdeen).

The twenty-first Annual General Meeting of the Medical Society for the Study of Venereal Diseases will be held on Saturday, July 25, at 2 p.m., at 11, Chandos Street, Cavendish Square, W. Mr. Aleck Bourne will give an address on non-gonococcal vaginal discharges, their diagnosis and treatment.

The 101st annual meeting of the Royal Medico-Psychological Association will be held at 11, Chandos Street, Cavendish Square, W., on Thursday, July 23, at 10 15 a.m., when, following the business part of the meeting, there will be a discussion on "Psychopathic Personality." The speakers will include Prof. D K. Henderson, Major D. C. Carrol, Surg. Capt D. Curran, Wing Cmdr R. D. Gillespie, and Lieut.-Col. A. A. W. Petrie.

The London Missionary Society announces that Mr. R. M Alderton, F.R.C.S., and Dr. Annie Sydenham, members of the Hong Kong staff of the society, are now interned in the Stanley Gaol in Hong Kong.

The Minister of Health visited last week "the country branch" of the London Hospital which has been completed at Brentwood, Essex. Taken over early in 1941 as an Emergency Medical Service hutted hospital, it is now a modern bungalow-type building with 360 beds. The work was financed by the Ministry of Health and the hospital is staffed and run by the parent institution. Much of the equipment has been brought from Whitechapel and the rest provided through the aid of "Bundles for Britain" and the Red Cross and St. John War Organization. A number of beds are reserved for cases for which the Ministry is responsible. The Minister said that this arrangement was part of the general desire for the Emergency Scheme to help the big London teaching hospitals in any way found to be practicable to maintain at least some of their work under their own identity in safer and more peaceful surroundings. He added: "Apart from the many thousands of extra hospital beds which we have provided in various ways under our Emergency Hospital Scheme, we have, under our building programme alone, added over 51,000 beds to the nation's hospital accommodation. The vast majority of these beds have been provided in the form of single-story hutments. Many form sturdy self-contained hospitals—complete with operating theatres and equipment down to the last detail. Others are extensions to existing hospitals."

Letters, Notes, and Answers

QUERIES AND ANSWERS

Autoserotherapy for Hay-fever

Dr. E. M. Fraenkel (Buxton) writes in reply to C. E B: I refer to my letter "Treatment of Allergy" in this *Journal* (1942, 1, 654). The simplest method for the practitioner is the use of the patient's blood. The blood is drawn from the cubital vein by a sterile syringe of 10 or 20 c.cm. and immediately injected into the gluteal muscle. I recommend the use of 10 c.cm. the first time, 15 c.cm. after 5 days, and 20 c.cm. again after 5 days' interval. In order to prevent clotting, 0.5 c.cm. to 1 c.cm. of a sterile 5% to 10% solution of sod. citrate can first be taken into the syringe.

Income Tax

War Damage Insurance

"Delta" showed in his income tax return £32 10s. paid for War Damage Insurance of his x-ray apparatus, and £7 4s, 50% of the contribution payable on his house. No deduction for income tax purposes is allowed for these payments. He has received £31 in respect of an x-ray tube that was damaged as a result of enemy action, and this sum has been deducted from his apparatus account.

*** Section 84 of the War Damage Act, 1941, provides that such payments shall not be taken into account for income tax purposes, but that sums received by virtue of the arrangements made under that Act have to be offset against expenditure on repairing or otherwise making good war damage. As "Delta" suggests, one would normally assume that if insurance contributions are not allowable for income tax purposes the resulting receipts should not be taken into account, but that view is overruled by the specific enactment referred to above.

LETTERS, NOTES, ETC.

The Medical Directory, 1943

J. & A. Churchill, Ltd, 104, Gloucester Place, Portman Square, London, W.1, write: To maintain the accuracy of our annual volume we rely upon the return of our schedule, which has been posted to each member of the medical profession. Should the schedule have been lost or mislaid we will gladly forward a duplicate upon request. The full names of the doctor should be sent for identification.

Films in First-aid Teaching

Films, and in especial colour films, have come to stay in the teaching of first-aid practice. It is essential that such films should be good both in matter and in the manner in which they have been produced. We recently described such a film taken in colour by Mr. B. H. Humble and Dr A. G. Mearns of Glasgow, and lately have had the opportunity of viewing another produced by Mr W. McAdam Eccles, who since the beginning of the war has been medical officer in charge of a central aid-post in London. The primary object of this film was to show to St. John and Red Cross personnel, particularly those who had not received their "baptism of blood," the precise details, on the night of a raid, of what actually occurs in a post receiving varied casualties. A whole night's work is depicted, and very well photographed, the work of an efficient amateur in the person of Dr. D. W. Seth-Smith. The film shows the organization of the aid-post, with nurses, orderlies, medical officers, and other workers engaged in their prescribed duties on a plan worked out with great thoroughness, and is an example of really good team work. Certainly no pains were spared to present casualties varied in type and differing in their seriousness. The film gives details of treatment which are of great value in teaching, such as are difficult to be grasped except by seeing them actually carried out. The treatment shown is necessarily that which is given by skilled persons in a well-appointed aid-post. In addition, methods of carrying the wounded, the need for quick perception of the gravity or otherwise of injuries, and the decision as to the disposal of the patients are all excellently portrayed Actual bleeding-points are controlled by digital pressure, by pressure forceps, and by suturing, as in the case of a bad scalp wound.

The producers had the invaluable help of Quartermaster J Magrill, B.R.C.S., whose skill as a designer of wounds and in stage management is great. Further, his spoken commentary as the film is thrown upon the screen shows him to be a master of the subject. It is, perhaps, unfortunate that a sound track of his comments has not as yet been made, so that the completed film could travel freely about the country and over-seas, and thus give that visual aid to many instructors now at work, and so bring new ideas and new interest before the keen persons in their classes The film is an 8 mm one and is silent, and its running time is about half an hour. We commend it unreservedly to all concerned in the efficient training of personnel who have to treat air-raid casualties. Applications to view it may be sent to: The Manager, Colour Film of Casualties, B.M.A. House, Tavistock Square, London, W.C.1.

MEDICINE 100 YEARS AGO

Extract from the *Provincial Medical Journal* of July 11, 1842:

"The poor man must have his doctor as well as the rich, and care should be taken that he be not driven, by expense, to seek advice from sources less competent than such as now supply it to him. The general practitioner should be upheld in making proper charges for his time and skill; but for many and obvious reasons, it would be unwise to deprive him of the power of dispensing his own medicines. If duly qualified practitioners acted under a public licence, the protection of the profession against unqualified and ignorant pretenders might well be left to the authorities of the state, and medical men would thus be relieved from the onerous and invidious task of prosecuting offenders; but the best protection of the profession is to be sought in an enlightened public, who, it must be acknowledged, are not backward in remunerating medical men for their services, and the skilful and duly qualified practitioner will always in the end have the advantage over the empiric and incompetent intruder."

BRITISH MEDICAL JOURNAL

LONDON SATURDAY JULY 25 1942

REHABILITATION IN THE E.M.S.

BY

Sir ROBERT STANTON WOODS, M.D., F.R.C.P.

Consultant Adviser in Physical Medicine, Member of the Committee on Rehabilitation, E.M.S., Ministry of Health

The Oxford Dictionary defines "rehabilitation" as "restoration to privileges." In the medical sense this would signify restoration to the privileges of health, so far as this is possible. In considering the rehabilitation of an individual it is logical to include not only the whole therapeutic procedure but also the mental and material environment to which he is subjected from the moment of the onset of his disease or the infliction of his injury. In the more restricted sense of the term, however, which alone is brought under survey here, efforts to rehabilitate can be considered under the heads of passive physical therapy or the application of physical agents, active (volitional) exercise, and productive occupation.

In many instances the whole of the programme may with advantage be started as soon as the patient arrives in a hospital bed. In general, it can be stated that, if there are no indications to the contrary, the earlier this special rehabilitation treatment is begun the better. Thus, for example, a patient who is admitted from the waiting-list for an abdominal operation will often benefit from pre-operational abdominal and general exercises; the precursors of an operation for an internal derangement of the knee may very usefully be faradic and "active" (volitional) contractions of the thigh muscles; while an individual with a lower limb in plaster ought to begin weight-bearing exercises as soon as he is ambulatory.

In the past a prescription of "rehabilitation" therapy has too often been made out with a view solely to recovery of the diseased or injured region, to the neglect of the general mental and physical make-up. Recent conceptions of the aims of treatment render it improbable that this error will persist; indeed, the danger is that the pendulum should swing too far, to the neglect of those other, equally indispensable, extrinsic factors—massage, electrotherapy, thermotherapy, etc.

Aims

In the strict sense of the term there is no form of treatment which can be designated "curative"; in choosing any therapeutic or prophylactic procedure, one's aim ought always to be to elicit such responses in the tissues and in the mentality of the individual as are likely to assist in the recovery or maintenance of health. To no part of medical or surgical treatment does this apply with greater force than to so-called "rehabilitation" therapy; the physical agents employed can, without gross exaggeration, be looked upon as tissue "insults," and it is necessary to be continually alert lest the insult be so gross, or the tissue so debilitated, that the latter is incapable of response, and consequent harm result.

The therapeutic effects of almost all these physical agents depend primarily upon a stimulation of the peripheral circulation—venous and possibly lymphatic in some cases, arterial in others. As regards massage, this is obvious. To the effects, however, of electrically stimulated muscle contraction a similar statement applies, and this therapeutic measure is an excellent instance of the ease with which the optimum dose of the tissue stimulus may be overstepped. Until recently the therapeutic effectiveness of this stimulus has been in dispute. Magladery and Solandt (1940) have, however, demonstrated that the wasting of denervated muscle can be retarded by such stimulation, properly applied. They have further shown that the maximum effective "time" dose is of the order of "a stimulus which is interrupted for 5 seconds every 5 seconds and applied for two minutes three times a day." This is in contradistinction to the method usually taught, in accordance with which a current of almost maximal intensity of stimulus is applied at a rate of about 2 per second with no prolonged pause, the whole treatment lasting up to 10 minutes or even longer—a total of stimulation time incomparably greater than that of Magladery and Solandt's maximum. This matter is worthy of stress, especially as, in a recent article (Gutmann and Guttmann, 1942), the statement appears that "the galvanic exercise treatment is the more successful the more the individual [denervated] muscles are exercised." Over-stimulation of such wasted and grossly abnormal muscle is entirely comparable to the administration of large doses of strychnine to a failing myocardium. A similar caution is relevant to all physical, as indeed to all therapeutic, agents. The dose must be graduated in accordance with the residual capacity of the individual and of his tissues to respond; an adequate dose for one would constitute gross over-stimulation in another.

Certain conditions also are notoriously sensitive to excessive *active* use: that in which the danger is most commonly recognized is dislocation of an elbow, especially in children or adolescents, though certain derangements of the knee are also susceptible. On the other hand, the safe or rather optimum degree of activity can often be assessed only after trial, under skilled medical supervision. Every rehabilitation department ought therefore to be continually supervised by a medical man skilled in the use of physical agents. Reference will be made later to the lack of this feature in the majority of hospitals otherwise well equipped, and to the reasons for this defect.

There is a growing tendency to decry the value of so-called passive therapy and to depend almost entirely upon the therapy of active function. Both are indispensable and can often be usefully employed concurrently at certain stages in the history of an injury or an ailment. Where normal tissue function is for any reason suspended, and tissue nutrition, through defective blood supply, is in consequence suffering, artificial stimulation of functional and vascular activity may partially replace normal conditions. One of the most striking and tragic illustrations of neglect of this principle is the permanently board-like hand which may result from the complete immobilization, with weight extension and without physiotherapy, of an upper limb for a high humeral fracture. "Passive" and "active" therapy do not constitute stages in treatment. Voluntary effort ought to form part of rehabilitation treatment at as early a stage as it may do so with safety, and passive therapy is with advantage often continued long after recovery of function has begun.

Provision in the E.M.S.

In the Emergency Medical Service there is very extensive provision of facilities for all these activities. Because in time of war the great preponderance of disability in the Services is due to injury, while in totalitarian war a large proportion of civilian disability is also due to enemy action, the earliest hospitals in the E.M.S. to be fully equipped in this respect were the so-called orthopaedic centres. At each of these there have for some time existed departments of physiotherapy of

4255

local and general remedial gymnastics, and of occupational therapy. At every such centre which has been enlarged by the building of hutted extensions these activities are housed in several specially designed huts; while at those centres at which the original hospital buildings did not necessitate this enlargement, suitable indoor spaces have been allocated to these purposes and the appropriate structural alterations made.

It was, however, obvious from long before the beginning of the war that these comparatively few orthopaedic centres would be insufficient for the numbers of war casualties which occurred or arrived in this country. The next step, therefore, was a much wider provision of rehabilitation facilities in the Service, in accordance with a decision of the Minister that every Class I E.M.S. hospital of 300 beds and upwards should reserve and prepare enough space to accommodate physiotherapy and indoor treatment by remedial exercises.

Later still, three types of fracture department, "A," "B," and "C," were selected—"A" and "B" as parts of general hospitals for long-stay and short-stay fractures, respectively, while the "C" departments, for civilian out-patients, are situated partly in hospitals and partly in certain clinics. In connexion with the "A" departments, as full provision for rehabilitation treatment, in proportion to size, is being provided as at orthopaedic centres; while "C" hospitals and clinics have been chosen because they already possess rehabilitation facilities adequate to their functions.

The *housing accommodation* for such a rehabilitation department at a large, hutted orthopaedic centre consists of the following: (1) A building, 144 ft. by 24 ft., for massage, electrotherapy, radiotherapy, thermotherapy (including short-wave therapy in some), and the earlier stages of remedial exercise; at one end of the building are "offices" for the staff. (2) A gymnasium, 60 ft. by 24 ft., for more advanced local and general rehabilitation gymnastics. (3) A room or rooms for handicrafts and carpentry.

Outdoor space is generally available for the more active forms of therapy, and full use is made of this, and especially of football, cricket, tennis, and even golf facilities. Stereotyped "P.T." is dead.

In *equipping* these departments with technical apparatus, at first only the most simple types were provided, and particularly such types as would be in greatest demand for the treatment of battle and bomb casualties. Gradually, however, it has been possible to supply some of the more specialized forms of equipment, and the rehabilitation departments are becoming more and more elaborately set out, while at the same time the provision of unessential varieties of apparatus is avoided.

The *technical personnel* which are recognized as being necessary to carry out the varied treatment belong to three groups—namely, members of the Chartered Society of Massage and Medical Gymnastics, male physical-training instructors, and occupational therapists.

With such facilities as have just been briefly outlined, rehabilitation activities at a large orthopaedic centre are obviously extensive, complicated, and diverse. The simplest of these begin in bed, and it is now the routine in E.M.S. hospitals for every patient who is confined to bed to perform at stated times during the day such exercises as are medically advisable, so that when confinement to bed is no longer necessary the individual ought to find himself at a much more advanced stage of general fitness than he would have been under the former regime of almost complete passivity. Pre-operational exercise and muscle stimulation are also coming more and more into use, to the obvious advantage not only of the muscle groups at the site of operation but of the patient's general tone and resistance.

All those who are ambulatory ought to attend the various departments. In the so-called "physiotherapy" department the members of the C.S.M.M.G. not only administer the various therapeutic agents there in use but also supervise the earlier stages of remedial exercise, with patients singly or in groups and exercising either freely or by means of gymnastic apparatus.

Many large hospitals are now provided with physical-training instructors, in the majority of instances supplied by the Army gymnastic staff and consisting of N.C.O.s who, in addition to their instructional training, have undergone a special course of remedial gymnastics. As soon as a convalescent is capable of doing so, he joins one of the carefully graded groups for physical exercise. In its nature this is entirely divorced from the old "physical jerks," and is made up of a combination of more or less formal physical training with indoor and outdoor games. In the winter much of this treatment is carried out in the gymnasia, already described; but advantage is taken of any out-of-door space, and at many of the E.M.S. hospitals it is possible to make use of football, tennis, and golf rehabilitation.

Occupational therapy is a standard part of treatment at all orthopaedic centres and at every hospital with a "Group A" fracture department, and trained personnel for this work are increasing in numbers, the Ministry having instituted an intensive course of training at one of the orthopaedic centres. The remedial aspect of productive occupation is partly physical and partly psychological, and the occupations consist of light crafts such as weaving, basket-making, and wool-mat-making, as well as of heavier work, mainly carpentry. In addition to these, at many centres the hospital gardens function as remedial agents.

The fullest advantage cannot be taken of such a complex organization, in which the same patient is undergoing treatment in all the three main divisions of rehabilitation, unless there is an efficient system of timekeeping, and at some large E.M.S. hospitals such a system is in use. This is under the supervision of an *organizer*, whose duty it is to see that every patient observes his therapeutic time-table.

Medical Personnel.—It must therefore be obvious, and it is now officially recognized, that *specialized medical supervision* of these activities is essential to the complete efficiency of a rehabilitation department in order to ensure the correct application of all the methods and physical agents used and, of even more urgent importance, to hold the proper balance between activity and rest in a population consisting not only of convalescents but of convalescents at varying stages of recovery. This medical supervision, however, has provided the most difficult of all the problems in connexion with the organization, and it would be idle to suggest that the difficulty has been overcome. That it has not is due to the very great expansion of rehabilitation facilities under the Emergency Hospital Scheme—at the newly established orthopaedic centres, in all Class I hospitals of 300 beds and over, in the special fracture hospitals, and at certain other special centres, such as neuroses centres, head centres, etc.; whereas it is almost literally accurate to say that before the war there were no specialists in physical medicine attached to hospitals outside the Metropolitan Area and the comparatively few large provincial centres. Even in London a typical "sector," with a teaching hospital at its apex, might furnish one or at most two such individuals in normal times attached to the teaching hospital, while with wartime expansion there have sprung up in the sector four or five other centres each of which may at present contain two or three times as many casualty beds as its parent and each of which ought to be provided with a physical medicine specialist. In the extra-metropolitan "regions" the situation is even worse, and is being progressively aggravated by the withdrawal into the Army of ever greater numbers of medical men. This withdrawal threatens to render futile, owing to lack of candidates, a scheme for an intensive course of training of medical men in rehabilitation therapy set up under the Emergency Medical Service. The desirability of such medical supervision, now officially recognized, ought to be obvious; its virtual indispensability, however, is fully realized only after comparing centres where it exists with those where there is no such unified control.

The policy of the Ministry is, at any rate at present, not in favour of the setting up of rehabilitation "centres." After the war, however, it is almost certain that such institutions will be found necessary, and the present emergency might, if the individuals were available, lead to the equipment of a number of men and women with a training which would render them competent to supervise a form of therapy whose post-war establishment will represent a great and long-advocated advance in the treatment of injury and disease.

DIPHTHERIC HEART-DISORDERS IN CHILDREN

BY

C. NEUBAUER, M.D.

R.M.O., City Hospital for Infectious Diseases, Walker Gate, Newcastle-upon-Tyne

Among all the ill effects which diphtheria may cause in childhood the damage inflicted on the heart is the most serious. The vast majority of deaths in children due to this disease occur as a result of injury to the cardiovascular system. A few cases of the laryngeal type result in death from mechanical obstruction and some others from pharyngeal paralysis. Practically all the remaining deaths are due to some form of cardiac failure.

Knowledge of the pathology, clinical signs, and treatment of diseases of the heart has been much increased in recent years by electrocardiography, and it is proposed to give an account of 100 cases of diphtheria with myocardial lesions observed from the onset to either convalescence or termination. These fall into three groups: (1) lesions of the heart musculature; (2) abnormalities of rhythm; (3) interference with conductivity.

The Myocardial Lesion

The clinical signs of this condition are well known. Chief among them are listlessness, pallor, and increase or decrease in the pulse rate. Albuminuria may be found, and when present to a marked extent during the early stages of the disease is regarded as a bad prognostic sign.

The Electrocardiogram.—Alterations of the T-wave, S–T stretch, or of both, are often found. The T-wave is low in comparison with the preceding P-summit, the height of which is normally half that of the T. In other cases the T-wave is either absent or inverted or diphasic, in which latter case the inverted part is followed by a final wave. These signs are regarded as pathological in children if they occur in lead I or leads I and II, or in all three leads. It has been shown in recent years that the degree of dislocation of the S–T stretch is of as much importance as variations of the T-wave in myocardial lesions, perhaps of even greater importance. The S–T stretch is compared with the level of the preceding P–R stretch to estimate its dislocation. Slight dislocation of less than 0.5 mm. may be disregarded, but any dislocation exceeding 1 mm. is pathological. It must be remembered that variations of this type are seen normally in lead III, that a flat or diphasic T-deflection may appear in lead II in children with meteorism, and that after treatment with digitalis the S–T stretch is dislocated and the T-wave flattened in lead II. If these variations are kept in mind the abnormalities in the electrocardiogram can be considered as due to myocardial damage caused by the diphtheric toxin. Indications of the pathological changes in the myocardium are sometimes found when the clinical signs are still doubtful. At the same time evidence of myocardial damage is sometimes still found when clinically the child appears to be quite recovered. The importance of the latter fact is obvious. At this hospital no child who has had a myocardial lesion is discharged until the electrocardiogram has returned to normal. Failure to ascertain that a myocardial lesion has completely cleared up may account for reports about slow recovery after diphtheria in certain cases, and for those tragic instances when a child dies suddenly at home after discharge from hospital. The electrocardiogram returns to normal again after 3 to 4 weeks in light cases, after 6 to 7 weeks in moderately severe cases, and after 10 to 13 weeks in severe cases in which a myocardial lesion is present without any disturbance of conductivity. In the present series of cases 38% show evidence of myocardial damage without any disturbance of conductivity. Some examples of variation in the T-wave and S–T stretch in cases of diphtheric myocarditis are shown in Figs. 1–6. All of them are lead II.

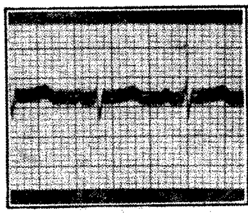

FIG. 1

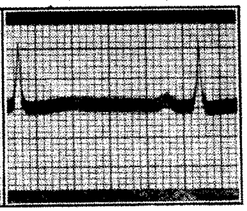

FIG. 2

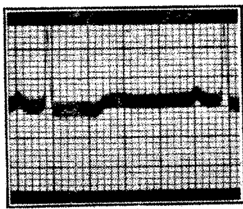

FIG. 3

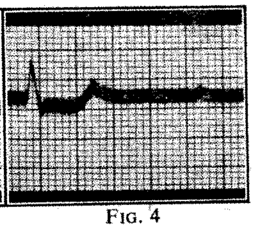

FIG. 4

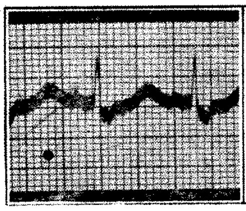

FIG. 5

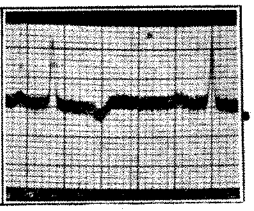

FIG. 6

FIG. 1.—T-wave very low
FIG. 2.—T almost isoelectric.
FIG. 3.—S–T stretch dislocated, T diphasic.
FIG. 4.—S–T dislocated and almost horizontal.
FIG. 5.—S–T a steep line, connecting S with T.
FIG. 6.—S–T dislocated, T inverted.

Abnormalities of Rhythm

Sinus Tachycardia.—Sinus tachycardia is very often seen during the febrile period of diphtheria, and is of no special significance. Tachycardia which persists into later convalescence should be carefully investigated. If the tachycardia is due to a myocardial lesion, evidence of the latter will be found together with the signs of the tachycardia.

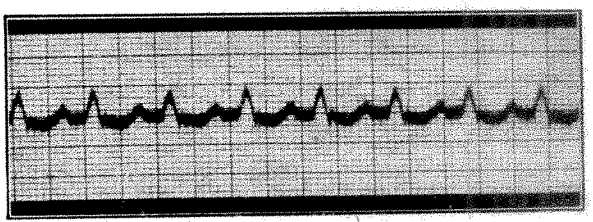

FIG. 7

Case 1: Fig. 7.—Beryl H., 4½ years; 29/12/1941; 15th day of disease.

Lead II: Regular tachycardia, rate 120. R notched; voltage 4/10 mV; duration 0.12 sec. S–T below the base-line. T diphasic.

Sinus Bradycardia.—Bradycardia is often found in the early convalescent stages of diphtheria as in other infectious diseases. The condition may, however, be due to cardiac damage. Gross bradycardia should always be carefully investigated to exclude a cardiac lesion. An electrocardiogram enables a differential diagnosis to be made at once.

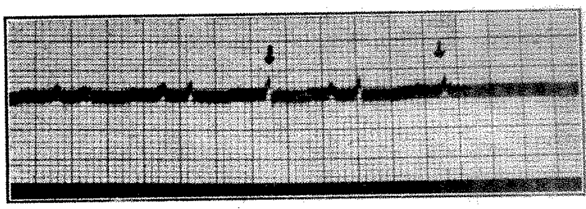

FIG. 8

Sinus Arrhythmia.—Sinus arrhythmia is a common cause of cardiac irregularity in childhood and has no pathological significance. It should be carefully distinguished from more serious forms of irregularity, as otherwise the activity of a healthy child may be quite unnecessarily restricted.

Extrasystoles.—Extrasystoles are not generally regarded as of serious import, and to a certain point the same may be said of them when they occur during the course of diphtheria.

Case 2: Fig. 8.—Robert L., 5 years; 22/8/1941; 22nd day of disease.

Lead II: P–R 0.23 sec. (partial a.-v. block). Ventricular complex of very low voltage; splintered and notched. T inverted. There are two extrasystoles, indicated by arrows.

Interference with Conductivity

The Auriculo-ventricular Block

Partial a.-v. Block.—This is a serious condition in which there is a lesion either of the a.-v. node itself or of the bundle of His and the surrounding myocardium. It occurs in severe infections, mostly of the gravis type. Clinical evidence of the condition is limited to bradycardia together with enlargement of the heart, but a definite diagnosis is impossible without an electrocardiogram. This latter shows a lengthening of the P–R interval, which normally in children does not exceed 0.12 second. A P–R interval of 0.2 second or more must be regarded as definitely pathological. Partial a.-v. block was found in 17% of the present series.

Case 3: Fig. 9.—Rosalie B., 3 years; 18/10/1941; 13th day of disease.

Lead II: Action regular. P–P 1.47 sec. Rate 40. P–R 0.36 sec. R notched near the peak. S–T below the base-line. T upright.

Complete a.-v. Block.—Clinical signs. An early symptom of the condition is often a syncopal attack in which the child is blanched and collapsed. The most marked feature is the extreme bradycardia, the pulse rate dropping to 30–40 a minute. Following a syncopal attack the patient remains pale and cyanotic, with coldness of the face and extremities and a livid tinge in the cheeks. The expression is anxious and there is often precordial or abdominal pain, together with marked restlessness and vomiting. Within one or two days the liver shows evidence of enlargement. Complete a.-v. block was found in 5% of the present series.

The electrocardiogram shows that the P-summits occur at equal intervals. The ventricular complexes also occur at equal intervals, but their rate is much less than that of the auricles. The varying length of the P–R intervals shows that there is no connexion between the auricular and ventricular contractions.

Case 4: Fig. 10.—Rosalie B., 3 years; 20/10/1941; 15th day of disease.

Lead II: P–P 0.65 sec. Auricular rate 92. R–R 2.00 sec. Ventricular rate 30. The auricle is beating three times more quickly than the ventricle. It is a 1:3 block. R widened and notched; duration 0.18 sec.; voltage 1/4 mV. T upright.

Lead III: P–P 0.65 sec. Auricular rate 92. R–R 2.30 sec. Ventricular rate 26. Duration of ventricular complex 0.14 sec. T inverted.

Bundle-branch Block

Partial Bundle-branch Block.—In the present series 19% of the cases showed evidence of this condition, which, as in the case of partial auriculo-ventricular block, can only be definitely diagnosed by use of the electrocardiogram. This shows a prolonged duration of the ventricular deflection, which normally does not exceed 0.05 second. In this condition it may be prolonged to 1 second or more, while the ventricular deflections are seen to be splintered and notched.

Case 5: Fig. 11.—Francis W., 5½ years; 24/2/1942; 9th day of disease.

Lead I: Action regular. R–R 0.75 sec. P indiscernible. Ventricular complex of low voltage. R splintered and thickened; duration 0.1 sec. S–T below the base-line. T isoelectric.

Lead II: P–P 0.80 sec. Rate 75. P–R 0.20 sec. Ventricular complex splintered at the peak; voltage 6/10 mV; duration 0.1 sec. S–T far below the base-line. T diphasic.

Lead III: R–R 0.80 sec. P indiscernible. Ventricular complex splintered and notched; voltage low; duration 0.05 sec. T isoelectric.

Complete Bundle-branch Block.—This condition occurred in 4% of the present series. The chief characteristics seen in the electrocardiogram are that R, S, and T waves are of high voltage; that a marked R-deflection is followed by an inverted T, while an exaggerated S-deflection is followed by an upright T, and that the duration of the ventricular complex is prolonged together with splintering and notching of the deflections.

Case 6: Fig. 12.—Ronald R., 5 years; 4/9/1941; 10th day of disease.

Lead I: P–R 0.31 sec. R splintered and notched; voltage 7/10 mV; duration 0.15 sec. T inverted.

Lead II: Voltage of S 1¼ mV; duration 0.11 sec. T upright.

Lead III: Exaggerated S; voltage 1 mV; duration 0.14 sec. T upright.

Left bundle-branch block.

Case 7: Fig. 13.—Jean W., 2 5/12 years; 25/2/1942; 8th day of disease.

Lead I: P–P 0.82 sec. Auricular rate 73. S–S 2.39 sec. Ventricular rate 25. S splintered; voltage 6/10 mV; duration 0.14 sec. T upright.

Lead II: Auricular deflection almost indiscernible. S–S 2.10 sec. Ventricular rate 28. Ventricular complex shows a notched downward deflection, the voltage of which is 1/3 mV, the duration 0.1 sec.

Lead III: Ventricular complex shows a very high R; voltage 1¼ mV; duration 0.1 sec. T inverted.

Right bundle-branch block.

Auricular Fibrillation

The electrocardiogram has shown that auricular fibrillation does not only occur in severely damaged hearts, but may also be seen as a transitory phenomenon in children when the heart muscle is undamaged.

Transitory Auricular Fibrillation.—This condition may arise in children during diphtheria, and may last a few hours or a few days. No abnormal clinical signs can be detected either before or after the attack, and the patient is not disturbed or distressed. The prognosis is good. The electrocardiogram shows typical auricular fibrillation, but there are no other signs of myocardial damage. The condition occurred in 2% of the present series.

Case 8: Fig. 14.—Irene G., 5 years; 9/10/1941; 29th day of disease.

Lead II: Action irregular. R–R 0.56 to 0.64 sec. Ventricular complex of normal configuration; voltage 8/10 mV; duration 0.05 sec. P-summits absent. The ventricular deflections are connected by oscillations. T-waves deformed by oscillations falling with them.

Lead III: Action irregular. R–R 0.60 to 0.63 sec. P absent. Ventricular complex of normal configuration; voltage 6/10 mV; duration 0.05 sec.; connected by oscillations.

Two days later the electrocardiogram did not show anything abnormal. The child had a normal convalescence.

Auricular Fibrillation in Severe Heart Lesions.—Patients who develop this condition show signs of myocardial damage for a period, sometimes long and sometimes short, before the onset of auricular fibrillation. The prognosis is very poor, especially in those cases in which congestion was present before the fibrillation started. According to Lewis, "the auricular fibrillation loads the already defective muscle with an extra burden." The electrocardiogram shows all the signs of a severely damaged heart muscle.

Case 9: Fig. 15.—Robert B., 3 years; 12/2/1942; 55th day of disease.

Lead I: Action irregular. P indiscernible. There are oscillations in the first cycle. Ventricular complex: voltage very low (1/4 mV). S–T on the base-line. T round.

Lead II: Action irregular. P absent. There are oscillations connecting the ventricular deflections, which are of low voltage (1/2 mV). T round and deformed by oscillations.

Lead III: Action irregular. P indiscernible. Voltage of ventricular complex 1/2 mV; duration 0.05 sec. T very low in some cycles, isoelectric in others. There are oscillations between the ventricular complexes.

The Occurrence of Death from Diphtheric Heart-disorders in Children

Death may occur, sometimes with startling suddenness, in the first ten days of the disease. This often happens in severe cases of the nasopharyngeal type due to the gravis strain of the organism. The fatal issue in these cases is usually brought about by one of three conditions:

A. *Gross Myocarditis.*—The electrocardiogram shows evidence of extreme myocardial damage.

Case 10: Fig. 16.—Alan W., 9 years: admitted 26/7/1941. Onset 25/7/1941. Severe nasopharyngeal diphtheria. K.L.B.+. Anti-diphtheria serum 60,000 units intravenously. 28/7/41: Membranes separating. 2/8/41: Vomiting, pallor, cold extremities; blood pressure 110/84. 3/8/41: Electrocardiogram taken 12 hours before death.

Lead I: Action irregular. R–R 0.85 to 0.87 sec. P imperceptible. Ventricular complex splintered; voltage 1/5 mV; duration 0.16 sec. S–T dislocated. T isoelectric.

Lead II: R–R 0.85 to 0.89 sec. P absent. Ventricular complex shows a downward deflection of 1/5 mV voltage and 0.15 sec. duration. T faintly indicated.

Lead III: R–R 0.80 to 0.87 sec. P indiscernible. Ventricular complex: voltage 1/3 mV, duration 0.1 sec. T isoelectric.

B. *Acute Complete Heart-block* (*Case 11: Fig. 17*).—Rosalie B., 3 years. Onset gradual, about one week. Admitted 11/10/1941. Severe pharyngeal diphtheria. K.L.B.+. Anti-diphtheria serum 30,000 units intraperitoneally. 12/10/41: membranes separating. 16/10/41: blood pressure 76/63. 18/10/41: syncope; partial a.-v. block; myocardial lesion. 19/10/41: complete heart-block; pulse 36; cardiac dullness enlarged; liver swollen; vomiting. 20/10/41: pulse rate 20; cyanosis; electrocardiogram taken 2 hours before death.

Lead III: Complete a.-v. block. Auricular fibrillation.

C. *Ventricular Tachycardia* (*Case 12: Fig. 18*).—Brian D., 3 years, admitted 13/12/1941; 4th day of disease. Severe nasopharyngeal diphtheria. 60,000 units anti-diphtheria serum intraperitoneally. Extremely ill; pale; hands and feet cold. Heart enlarged; "tick-tack" rhythm. Electrocardiogram shows complete heart-block. 12 p.m.: Child very restless; pulse weak. 14/12/41: semi-conscious; cyanotic. Offensive oral fetor. Electrocardiogram taken 1/2 hour before death. Regular tachycardia. R-R 0.49 sec. Rate 122. P indiscernible. The ventricular complexes are atypical, and one complex follows the other without any interval. Duration 0.18 sec. T diphasic. There is a longer interval after the last cycle in the third lead.

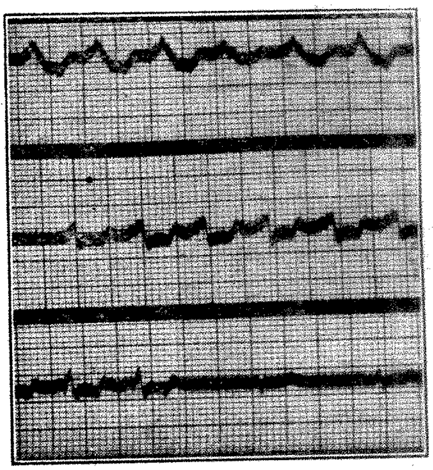

FIG. 18

The examples given above are sufficient to show that electrocardiographic investigation in support of careful clinical examination of the patient is desirable in the treatment of any case of diphtheria other than the mildest, and especially when there is reason to suspect the presence of myocardial damage. It is only by the use of the electrocardiogram that a clinical suspicion of myocarditis can be definitely confirmed.

In general it is possible to discharge a patient who has suffered from a mild attack of diphtheria in four weeks, from an attack of moderate severity in six to seven weeks, while those with a severe infection may have to be retained in hospital for three months or longer. Where evidence of a myocardial lesion has been found the patient should not be discharged until the electrocardiogram has returned to normal.

I wish to express my thanks to Dr. J. A. Charles, medical officer of health, Newcastle-upon-Tyne, for permission to carry out the investigation, and to Dr. E. F. Dawson-Walker, medical superintendent of the Hospital for Infectious Diseases, Walker Gate, for assistance in the preparation of this article.

A CASE OF INTRA-UTERINE INFECTION OF THE FOETUS BY GAS-GANGRENE ORGANISMS

BY

F. H. KEMP, M.B., M.R.C.P., D.M.R.
Assistant Radiologist to the Radcliffe Infirmary

AND

J. A. STALLWORTHY, F.R.C.S., M.R.C.O.G.
Assistant Obstetrician and Gynaecologist to the Radcliffe Infirmary

The following case is recorded as one of unusual clinical and radiological interest.

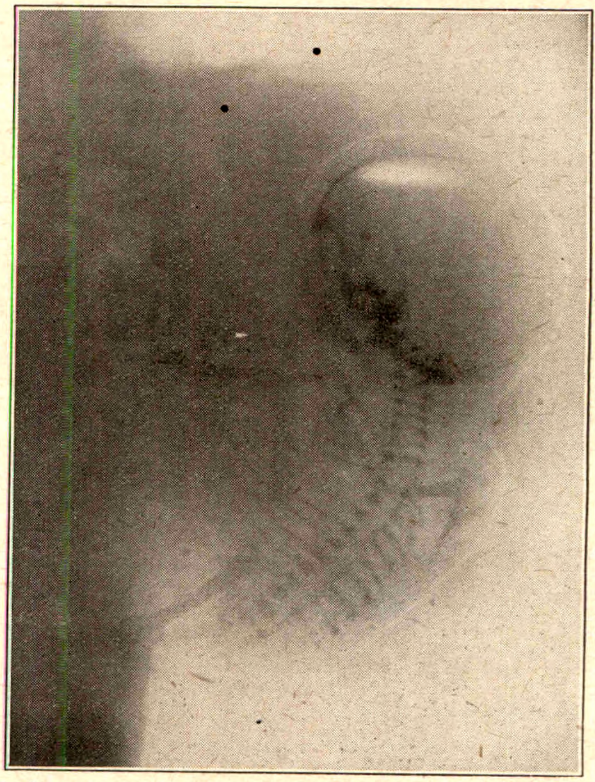
Case Report

The patient, a 2-para aged 30, was 16 weeks pregnant when she first attended the ante-natal clinic at the Radcliffe Infirmary in November, 1940. Her first child, weighing 6 lb. 11 oz., was born in 1930, and the second, weighing 9 lb. 8 oz., was stillborn the following year. Two months after the second confinement it was discovered that the patient was suffering from diabetes mellitus, and it would seem probable that this condition was present during the pregnancy and was responsible for its unfortunate ending. From the time diabetes was diagnosed in 1931 until the patient attended the Radcliffe Infirmary in 1940 she had required 30 units of insulin daily, and at her first ante-natal examination she was found to have just a trace of sugar in the urine, but no acetone or albumin.

Obstetrical progress was uneventful until Feb. 7, 1941, when complaint was made of sickness, and hydramnios was found to be present. The blood pressure was 110/80, and the urine was free of sugar and albumin. Foetal parts could not be felt, and, to investigate the cause of the hydramnios, a radiograph was taken. One apparently normal foetus presenting by the vertex was reported. The following week there was a considerable increase in the size of the uterus; acetone and sugar were present in the urine, but there was no albumin. The patient was more uncomfortable and was admitted to hospital. The foetal heart was audible and foetal movements were felt. In the next 10 days the abdomen increased rapidly in size and oedema of the lower extremities occurred. At this time the foetal heart could not be heard, so a second radiological examination was made on Feb. 27. It revealed a breech presentation but no overlapping of the skull bones or other features suggesting foetal death. On March 4 the patient stated that she could not feel any foetal movements, and no foetal heart could be heard.

On March 8 a further radiograph revealed a breech presentation with slight overlapping of the skull bones and a large bubble of gas within the shadow of the foetal head (see Fig.). Other films taken with the patient standing upright demonstrated gas and a fluid level within the foetal skull. The foetal brain and its investing membranes seemed to have collapsed, as the air bubble could readily be displaced to different positions by changing the woman's posture. No other bubbles of gas were seen within the foetus. The previous films were re-examined, and the second radiograph, taken on Feb. 27, showed several smaller gas bubbles within the shadow of the foetal skull which could not be accounted for by gas in the mother's intestinal canal. The diagnosis was that of intra-uterine foetal death, and it was suggested that there was a gas infection of the foetal skull. Arrangements were made for the pathological laboratories to investigate the foetus bacteriologically as soon as it was delivered.

On March 16 spontaneous delivery of a macerated foetus occurred. The foetal body was soft but the skin was intact. Within an hour of delivery radiographs were taken of the foetal body and the presence of gas in the skull was confirmed. No further collection of gas was seen in any situation. The skeleton was well developed and both lower femoral epiphysial centres were ossified. Dr. A. H. T. Robb-Smith opened the skull, and some of the macerated cranial contents were taken for bacteriological examination. There was extreme maceration but no naked-eye appearance of gas infection of the tissues. Sections from the brain and liver showed an extreme degree of autolysis, but no gas-forming organisms were seen. Bacteriological culture of the smears taken from the cranial contents was reported by Dr. Vollum to show a pure culture of an organism which was identified as *Cl. welchii*. The puerperium was uneventful, and except for a temperature of 99° on the third and fourth days it was apyrexial.



Radiograph taken on March 8. Intracranial gas bubble is well shown.

It is interesting to note that on Dec. 28, 1941, this patient was delivered of a healthy living female child after spending many weeks in hospital so that her diabetes could be controlled.

Discussion

This is a case of intra-uterine infection of the foetus with gas-forming organisms occurring in a woman suffering from diabetes mellitus. Hydramnios and increasing oedema of the lower extremities developed at the thirty-second week of gestation, and at this time there was considerable difficulty in controlling diabetes. A fortnight later, at the thirty-fourth week, there were signs suggesting foetal death, and radiographic examination revealed bubbles of gas within the foetal skull. Seventeen days after this a macerated foetus was delivered and a pure culture of *Cl. welchii* was obtained from its intracranial contents. There was no evidence of maternal toxaemia due to gas-forming organisms either before or after delivery. It would appear that the foetus died 17 or 18 days before delivery, as the heart had been heard on Feb. 25 but not on the 27th. The films taken on the 27th revealed small collections of gas in the foetal skull. Presumably the infection occurred after the death of the foetus, although it is possible that it was the cause of death. It is difficult to explain the path of infection: there had at this time been no interference and no vaginal examination had been made. There was no evidence of a low-lying placenta and no apparent focus of infection elsewhere in either the mother or the infant. It would seem, therefore, that infection was blood-borne and transmitted through the placenta. Unfortunately the placenta was not examined bacteriologically. It is also difficult to know why infection was localized to the foetal skull, especially in view of the fact that gas was known to be present for 17 days before delivery and was detected in no other organ either by radiological examination or at necropsy. It is known that the liquor was not grossly infected, for no gas was present in the amniotic sac. Had the foetal skull been opened during the process of birth a pure culture of *Cl. welchii* would have been liberated in the genital tract. That this is possible should be considered when perforation is performed on a dead foetus or when Willett's forceps are applied to the scalp of such a foetus.

The relevant questions to be answered are: How often does gas infection of a foetus occur, and what is the path of infection? It is not uncommon for gas to be seen in all the principal vessels of the body within 24 hours of delivery, presumably secondary to infection of the placenta or the vessels of the umbilical cord; but one of us has investigated 8 cases, in addition to the one recorded, of suspected foetal death by examining the mother in the erect position, and no gas shadows have been observed.

THIOUREA AND WOUND REPAIR

BY

W. R. FEARON, M.B., Sc.D., F.I.C.
Department of Biochemistry, University of Dublin

The value of local applications of urea in the treatment of septic wounds was demonstrated in 1915 by Symmers and Kirk, and has been confirmed by many subsequent workers, including Millar (1933), Foulger and Foshay (1935), Robinson (1936), Muldavin and Holtzmann (1938), and Stonham (1941); while Cummins (1942) has shown that urea in concentrated solutions is an effective bactericide.

In 1929 Hammett reported that mitotic division and cell proliferation during wound repair were promoted by certain organic compounds containing a thiol, or sulphydryl group, and he advanced the theory that tissue reconstruction was associated with the presence of free –SH groups (Hammett and Reimann, 1929), an explanation also put forward by Rapkine (1930), and accepted by Riley (1940) in an important survey.

Now, thiourea, the sulphur analogue of urea, resembles urea in many of its properties, and, furthermore, contains a latent or masked –SH group; consequently, its possible therapeutic effect in wound repair appears worthy of investigation. Thiourea is of very low toxicity, and may be obtained in a pure form, since its solubility in water at ordinary temperature is only about 1 in 30, which is much less than that of the ammonium thiocyanate from which it is prepared. Thiourea is much more stable than the typical thiol compounds. Its aqueous solution may be sterilized by boiling, and keeps well, although long exposure to air and light results in some decomposition, as shown by the gradual appearance of a precipitate of sulphur and dicyanamide.

Clinical Reports

For the preliminary investigation, ulcers of the static chronic type were selected for treatment. Two series of observations were made, the first being undertaken by J. G. Waugh, M.B., B.Ch., of this University, to whom I am indebted for the following report:

Fifteen cases were treated, in which the ulcers were characterized by extreme chronicity and recurrence due to fibrosis, exposure to trauma, poor blood supply, or polysepsis. After preliminary cleansing, the thiourea was applied in the form of a 1% aqueous solution on a gauze dressing kept freely moist with the reagent. Application in all cases was followed by a brisk local reaction, accompanied by convergence of the epithelial margin. The response increased up to the eighth day and in some cases progress continued up to the twelfth day. After this, application of thiourea had no further obvious effect, and if persisted in merely tended to soften and macerate the epithelial margin.

The second series of cases was investigated by E. Kawerau, M.B., B.Ch., the treatments being carried out in Dublin at Dr. Steevens's Hospital and at the Adelaide Hospital.

Thirty-two cases were treated, the subjects being mostly working-class women beyond middle age. In all of them the ulcers were due to a varicose condition of the veins of the leg, and in more than half had a chronicity of over 5 years. Observation of all the cases showed that thiourea has a definite stimulative effect on the proliferating granulation tissue. When conditions are favourable the optimal response is reached within 12 days, although large ulcers of 0.5 cm. depth have filled with healthy granulation tissue up to their epithelial margins within a week. When this has occurred the treatment should be discontinued, as otherwise fibroblastic proliferation becomes exuberant and impedes epithelial growth, as already pointed out by Riley.

Method of Treatment

The procedure adopted in applying the thiourea is important. The most effective results followed the use of a 1% aqueous solution of thiourea (B.D.H.), applied on gauze or lint and kept moist by renewal every three to four hours. If the dressing is allowed to dry it adheres to the granulating surface, and is apt to cause damage when the dressing is renewed. If evaporation is prevented by use of a completely occlusive covering over the dressing, there may, for some unexplained reason, be considerable local pain. The difficulty of providing a continuously moist dressing for externe patients was overcome by the use of a hygroscopic paste, prepared by boiling 1 g. of thiourea and 2 g. of starch in 100 ml. of water. When the mixture had become of uniform consistency it was allowed to cool, and then 5 ml. of glycerol was added. This paste was applied on gauze or lint cut so as to fit the ulcer surface accurately. This was covered with a larger piece of lint, a thin layer of cotton-wool, and finally a broad bandage. No occlusive material is used. Where practicable the dressing is reapplied daily.

Conclusion

The mechanism of the action of thiourea and the other thiol compounds effective in promoting wound repair awaits elucidation. The only physiological property so far ascribable to thiourea is that of inhibiting the catalytic oxidation of ascorbic acid in aqueous solution (Fearon and Kawerau, 1942). As ascorbic acid is intimately associated with collagen formation and fibroblastic growth (Eddy and Dalldorf, 1941), the therapeutic action of thiourea may reside in its protective effect on the vitamin mobilized locally for tissue repair.

I wish to record my thanks to my two collaborators for the trouble they have taken in the clinical investigation of the action of thiourea; I also gratefully acknowledge the grant from the Medical Research Council of Ireland, which has made it possible for Mr. Kawerau to undertake his part in the work. The case histories and details of individual treatment will be published elsewhere.

F. R. Whitehouse and C. H. Watkins (*Proc. Mayo Clin.*, 1942, 17, 140) record a case of multiple diseases of the lungs treated by sulphadiazine. After the second course of this drug the patient had severe bleeding from the gums, and thrombocytopenia was detected, the platelets numbering on one occasion only 20,000 per c.mm. The value for Hb was 10.5 g. per 100 c.cm. of blood. The drug was discontinued, and improvement resulted from a transfusion. Four weeks after this the patient had to be given sulphadiazine again, and thrombocytopenia recurred. The authors urge that thrombocytopenia as the result of sulphonamide therapy should always be suspected when purpura occurs during treatment.

CERVICAL RIB AND HYPERHIDROSIS

BY

E. D. TELFORD, B.Chir., F.R.C.S.

Emeritus Professor of Surgery, University of Manchester

(From the Neurovascular Clinic, Manchester Royal Infirmary)

The usual signs that a cervical rib is causing trouble are pain and muscular weakness. It is also generally recognized that in some instances there are vasospastic phenomena which may lead to gangrene of one or more fingers.

A consequence of cervical rib which is not so widely known is hyperhidrosis of the hand; the sweating here may be profuse and very troublesome. In a series of 92 patients on whom I have operated for symptoms of cervical rib there were 81 of the common textbook type. Of the remaining 11 cases, 5 were examples of pressure by a normal first rib, 4 showed predominantly vascular symptoms, while 2 patients complained mainly of profuse hyperhidrosis of the affected hand. Short notes of these two cases are as follows:

Case I

A housewife aged 38 had for some weeks felt an aching and weakness of the right hand, with very profuse sweating. She was right-handed, and her troubles were worse at the end of a day's work. When seen her right hand was normal in colour and temperature, but was covered with drops of sweat, which had saturated the bedclothes where the hand rested. Operation showed a large cervical rib articulating by a fibro-cartilage with the first rib at the scalene tubercle. The accessory rib showed clearly the groove in which the lowest trunk of the plexus had rested. Removal of the rib was followed by a rapid and complete return to normal.

Case II

A probationer nurse aged 18 had been perfectly well while working as a typist, but within 6 weeks of taking up nursing she complained of increasing weakness of the right hand, with aching pain and troublesome sweating. She was right-handed, and the cause of her trouble was no doubt the change from a light sedentary occupation to one of physically much heavier work. A radiograph showed a small cervical rib on the right side. At operation this rib was found not to extend as far as the plexus, but was continued as a tense fibrous cord in the substance of the scalenus medius. The lowest trunk of the plexus rested on this cord, and it was seen that with each inspiration the cord became taut and pressed so hard on the lowest trunk that this structure was lifted up with each breath. Division of this fibrous cord, together with section of the anterior two-thirds of the scalenus medius, was followed by prompt and complete recovery.

Commentary

It would seem well-nigh certain that the explanation of these cases of hyperhidrosis of the hand is to be found in the irritation by the cervical rib of those sudomotor sympathetic fibres which are running in the lowest trunk of the brachial plexus. This explanation is in line with that generally accepted for the vascular complications of cervical rib.

Todd (1913a, 1913b) was the first to suggest that these vascular phenomena were the result of irritation of sympathetic fibres. Telford and Stopford (1931) carried his work a stage further by showing that in some individuals the vasoconstrictor fibres passed through the lowest trunk of the plexus as an undistributed bundle, and that this bundle lay directly upon the cervical rib. Given a patient with cervical rib who has this disposition of sympathetic fibres, then the symptoms caused by pressure and friction on the lowest trunk will be predominantly vascular in type. This explanation, although widely accepted, has been challenged by some writers who still believe that the vascular symptoms are to be explained by mechanical interference with the subclavian artery. Be this as it may, mechanical interference with the artery will not explain hyperhidrosis of the hand; whereas the view that the excessive sweating is the result of sympathetic stimulation dovetails very neatly with the explanation of the vascular symptoms.

Sudomotor and vasoconstrictor fibres are known to be intimately associated throughout their course and distribution, and if a leash of fibres containing both types be exposed to irritation by friction or pressure, the factor of their relative position with regard to the rib will determine whether vasospasm or hyperhidrosis figures more prominently in the clinical picture.

DESERT SORES

BY

H. M. RAPPORT, M.R.C.S.

Captain, R.A.M.C.

The following article is in no sense intended to be authoritative or academic. It is merely a collection of views acquired after treating over 1,000 patients for desert sores.

The desert sore is a chronic ulcerative condition of the skin characterized by its tendency to local extension and delayed resolution. It appears in patches of various dimensions from the size of a threepenny-piece to that of a half-crown or occasionally even larger. The ulcers may be single or multiple; the edge is usually irregular in outline. They are roughly divisible into two main types—primary and secondary.

The primary type appears as a spontaneous blister which ruptures and leaves behind a suppurating sore. The secondary type is superimposed on any slight cut, abrasion, or burn. In this connexion it is interesting to note that the skin is far more susceptible to injury in the climate of the desert. The minimum amount of trauma will invariably result in a breach of the skin surface. A not uncommon origin for a desert sore is a simple boil which ruptures and then fails to resolve. Lastly, bites due to fleas, bugs, and mosquitoes occasionally suppurate and give rise to the desert sore.

Aetiology

The aetiology appears somewhat obscure, but certain factors without doubt tend to promote the condition. When the diet is seriously lacking in fresh green vegetables or the equivalents, I have noted a marked rise in the number of sores seen. The adequate provision of a comprehensive scale of rations naturally presents many difficulties in countries such as the Western Desert, where, on the whole, the rations are exceptionally good; but now and again essentials are lacking.

Patients tend to ignore their sores and leave them uncovered in the early stages. As a result, flies, which are very prevalent, tend to spread the condition. In the same way, the contact of sand with the sores tends to make them worse. When water is short, and washing as a result is on a very primitive scale, I find that the impregnation of dirt in the skin will often give rise to blisters, which subsequently become desert sores. General ill-health is usually associated with a profusion of desert sores, but in this connexion I find it difficult to differentiate between cause and effect. Very very occasionally when cases show rapid deterioration I have swabbed the sores, and the Klebs-Loeffler bacillus has been found. In my series of 1,000 cases 2 proved to be due to diphtheritic infection.

The condition is almost universal among the troops in the desert, but I find that newcomers are especially susceptible. The fair-skinned men seem to show the greatest susceptibility. An interesting feature is the presence of sores among the Egyptian and Libyan natives, several of whom I have treated. Their response to treatment is no better than that of our troops.

The lesions are, in my experience, seen chiefly on the extremities, and by far the commonest site is the hand. The actual sores are difficult to classify, but I recognize four stages:

(*a*) A small shallow ulcer with yellow base. The edges are not inverted, but there is a distinct tendency to undermining of the edges of the skin in close proximity to the sore, where pus forms, and eventually the ulcer elongates along these new channels. At this stage the sores are usually painful and tender.

(*b*) The sore has reached the indolent stage. It fluctuates between partial resolution and extension, and is now usually almost painless. Pus continuously exudes from the lesion.

(*c*) At this stage the sore becomes flush with the surface of the skin, with exuberant granulations, a dry scab forms, and the condition seems almost resolved. Then from one corner of the scab pus appears; the scab loosens and is eventually shed, and the base of the ulcer is once again a suppurating sore.

(*d*) Eventually in a shorter or longer time, which may vary from one week to six months, the sore heals and leaves a permanent purplish-blue scar.

Any of the sores may pass through one or more of these stages, but may remain for an indefinite period in stage *b*.

Treatment

The treatment from the point of view of prophylaxis is naturally the provision of a diet which is comprehensive in all essential material constituents, especially vitamin C. In the Army, ascorbic-acid tablets can be issued on medical recommendation at the scale of one 25-mg. tablet per man daily when the ration is considered to be deficient in vitamin C. This amount of ascorbic acid I prescribe in every case. All cuts and abrasions should be covered in the first instance to prevent access of flies and sand. Sanitation in the field must be of the highest possible order to reduce the fly menace to the minimum.

The general treatment consists in allowing the severe cases to rest from work entirely in the first instance. This may be impracticable, but an attempt should be made to release patients from all but the most essential duties. I find ascorbic acid in larger doses—1 tablet of ascorbic acid (25 mg.) t.d.s.—of considerable advantage. Where it has been possible to obtain tablets containing all vitamins these have been far more effective. When after several weeks of intensive local and general treatment patients fail to respond, or even show signs of marked deterioration, they have to be evacuated to the base hospital as there is no chance of recovery in the field. Local treatment in my experience has resolved itself largely into the question of "trial and error." Its effectiveness varies from one individual to the next. An agent which effects a rapid cure in one patient may exacerbate the condition in another, and vice versa.

After experimenting with many pastes, ointments, and powders I have found the following agents to be most generally effective:

(i) Powdered suphapyridine incorporated into paraffin. molle flav. (three 0.5 g. tablets of sulphapyridine to 2 oz. of paraffin. molle flav.). This is applied locally and the dressing renewed after three days. I have tried in a few cases scrubbing the sores with a nail-brush and applying elastoplast over the sore with sulphapyridine paste in direct contact with the sore; the process is painful and has, in my opinion, little advantage over that first mentioned.

(ii) Powdered sulphapyridine applied alone to the sore is sometimes effective, especially in stage *b*.

(iii) Lotio eusol is often helpful in those cases which only partially respond to (i). It often increases susceptibility to treatment with (i) if the patient has applications of eusol for a few days in between treatment with (i). Acriflavine 1 in 1,000 concentration is also in the same way sometimes effective.

(iv) Patients in stage *c* often respond well to pasta flava (pulv. hyd. oxid. flav. 3 parts, pasta zinci oxid. co. 97 parts).

I make it a practice never to persist in the application of any one agent longer than 2 weeks, as the sores seem to acquire a tolerance to it after a while. If a temporary change of agent is adopted for a few days I find that on resumption of the original agent its effectiveness is often increased. This tolerance to a particular agent is a very real one, and when the agent is persisted in I have frequently seen rapid deterioration. The advisability of "ringing the changes" must be carefully considered in cases not showing response to a particular treatment. In the treatment of all sores it is essential that they be completely covered to ensure freedom from contamination with extraneous matter. In the case of the fingers I find the application of splints a great aid to resolution and a distinct deterrent to chronicity.

Illustrative Cases

I have chosen 4 brief case histories which illustrate certain points I have previously mentioned:

Case 1.—A major aged 27, fair-skinned, seen first with five small sores on the fingers. Treatment was given as outlined earlier in this paper, and while some sores resolved, others remained weeping with no tendency to resolution. At the same time numerous new sores were appearing. After 15 weeks' treatment we reached a large town where diet was both liberal and varied. All his sores disappeared in 5 days.

Case 2.—A captain aged 37, dark-skinned; slow response to treatment. He went on leave to base, where he acquired tab. multivite (B.D.H.), which he took in a dose of 1 tablet thrice daily. He returned one week later with all his sores healed, and he has had none since.

Case 3.—A lieut.-colonel aged 43, medium complexion, had numerous desert sores which were very resistant to treatment until pasta flava was tried; these rapidly cleared up after three applications. In his case other agents tried caused exacerbation of the condition.

Case 4.—A quartermaster-sergeant aged 28, fair-skinned, seen first with numerous desert sores and widespread furunculosis. All treatment failed and his general condition made removal to hospital essential. He took 3 days to reach base hospital, and on arrival his lesions had entirely healed!

Conclusions

The condition of desert sores is one to which people normally domiciled in a temperate climate are very susceptible while living in the desert. Added to this is the difficulty of maintaining the diet on a basis comprehensive enough to ensure adequate amounts of essential foods and vitamins. Finally, the conditions attendant upon active service render adequate treatment difficult and the follow-up of patients is of a standard which compares unfavourably with what one might desire.

Medical Memoranda

An Obscure Cause of Haematemesis

A fatal case of haematemesis due to ingestion of foreign bodies seems worth recording, in virtue not of the nature of those bodies but of their location at necropsy.

CASE REPORT

An undersized and under-developed girl aged 16½ was admitted to the Worcester Royal Infirmary on July 29, 1941, having been ill for 5 days with pain in the lower part of her back severe enough to keep her in bed. It was noticed that she showed a morbid interest in her complaint. There was a history of pyelitis some years previously. On admission she was vomiting green fluid and there was tenderness in the left lumbar region of the abdomen; the urine was, however, without obvious abnormality. The temperature was 100.6° and the pulse rate 96. A tentative diagnosis of perinephric abscess was made and conservative treatment initiated. Thirty-six hours after admission the patient suddenly became restless and complained of thirst; she shortly afterwards started vomiting blood, some 20 oz. being lost over a period of several hours. In spite of restorative measures she deteriorated rapidly and died 5 hours later.

At the post-mortem examination, held 24 hours afterwards, the stomach was found to be distended with recent blood-clot, but there was no evidence of either gastritis or gastric ulcer. The spleen was normal in appearance. The pancreas was much enlarged, and on opening it a haematoma the size of an orange was seen to occupy most of the head and body of the organ. This haematoma showed organization at the periphery, but in one point there was a commencing abscess cavity. A sharp object was accidentally located in the haematoma; this proved to be a sewing-needle. On further exploration two other needles were found, half the eye of one of them being missing. The duodenum was then opened, and at the junction of the middle and distal thirds on the mesial wall an ulcer was found in direct communication with the pancreatic haematoma; it was rounded and admitted the tip of the little finger; the edges were injected, but the walls were not indurated. On opening the splenic artery a small haematoma was seen in its wall. This artery had apparently been penetrated by one or other of the needles, thus giving rise to the fatal haemorrhage, for the artery had presumably bled into the intrapancreatic haematoma already present, and the haematemesis was due to the passage of blood through the perforation of the duodenum into the stomach. On opening the intestines a fourth needle was encountered at the hepatic end of the transverse colon; it was embedded in the substance of the transverse mesocolon close to the bowel wall. This needle had presumably perforated the duodenum, travelling to its destination in the substance of the transverse mesocolon, the alternative and less probable route being through the small intestine and ascending colon with perforation of the large gut at the site where it was found.

COMMENTARY

References in the literature to the site of foreign bodies in the respiratory and intestinal tracts at various intervals after ingestion gave only one example of a foreign body having perforated a hollow viscus to enter another organ. Prof. Ameline (1937) instances a woman aged 68 who accidentally swallowed a glass-headed pin. She was admitted to hospital 7 days later. There were no physical signs in the abdomen and no symptoms except a subjective sensation of the pin having become lodged in the stomach. Repeated radiographs confirmed that the pin had perforated the posterior gastric wall. Fifteen days after the accident gastrostomy was performed. The pin was found embedded in the posterior wall of the stomach, the point being fixed in the pancreas. It was removed and the patient recovered.

In our case a history was obtained of the girl having previously swallowed other foreign bodies, but we could not get any information about the needles which caused her death.

Of 17 cases recorded—1 by Ameline (1937), 1 by Kennedy (1935), and 15 by Jackson and Jackson (1936)—of ingestion of pins and needles, 9 were found in the bronchi, 2 in the pharynx, and 4 in the oesophagus, while the remaining 2 were in the stomach.

The interesting features of this case are: the absence of any history of having swallowed foreign bodies, with resulting difficulty in diagnosis; the penetration of the pancreas, with expansion of the pancreatic tissue around the haematoma; and the perforation of the splenic artery, with subsequent aneurysmal rupture and fatal haemorrhage.

I am indebted to Mr. T. Bates for permission to publish this case, and to Dr. W. H. McMenemey, who performed the post-mortem examination, for his very kind help and criticism.

Diverticulum of the Jejunum

H. C. Edwards, in his *Diverticula and Diverticulitis of the Intestine* (Bristol, 1939), says that jejunal diverticula give rise to two main symptoms: (1) vague abdominal discomfort and sometimes pain, particularly after meals; (2) flatulence, sometimes very pronounced and associated with loud borborygmi. The condition is uncommon. Edwards found it only 9 times in 2,820 necropsies at King's College Hospital—an incidence of 0.31%. As this condition is unusual and presents difficulty in diagnosis, the description of a case in which dyspepsia with pain thought to be due to a duodenal ulcer was eventually proved to be due to a large jejunal diverticulum should be instructive.

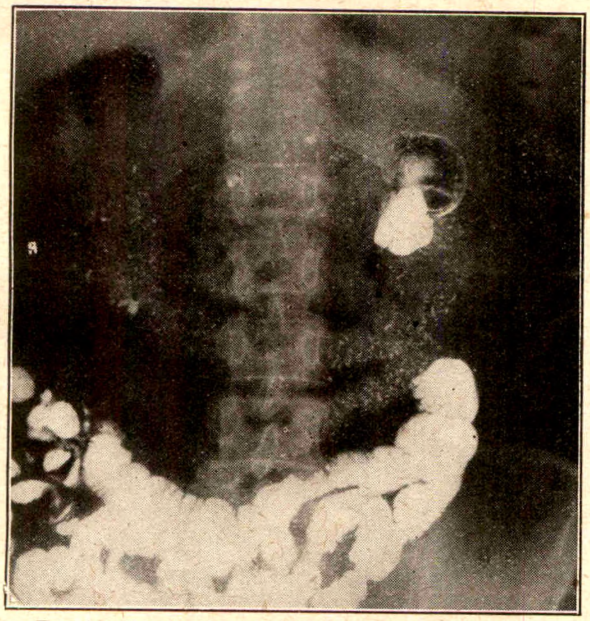

FIG. 1.—Showing barium filling the diverticulum of the jejunum 3 hours after injection of barium.

CASE REPORT

The patient, a married woman aged 56, had for more than 14 years complained of attacks of abdominal pain accompanied by much flatulence. In 1924 she had had a left nephrotomy for a large renal calculus; the history about this time is somewhat confused by the renal pain. From 1926 onwards the attacks of upper abdominal pain accompanied by much flatulence, which was relieved by bringing up gas and also by taking food, were well defined. In 1926 a laparotomy was performed after a diagnosis of duodenal ulcer had been made; but no ulcer was found, and the gall-bladder was normal. As a result of these findings, from 1926 until 1939 the attacks were treated symptomatically on the assumption that they were largely due to nervous dyspepsia.

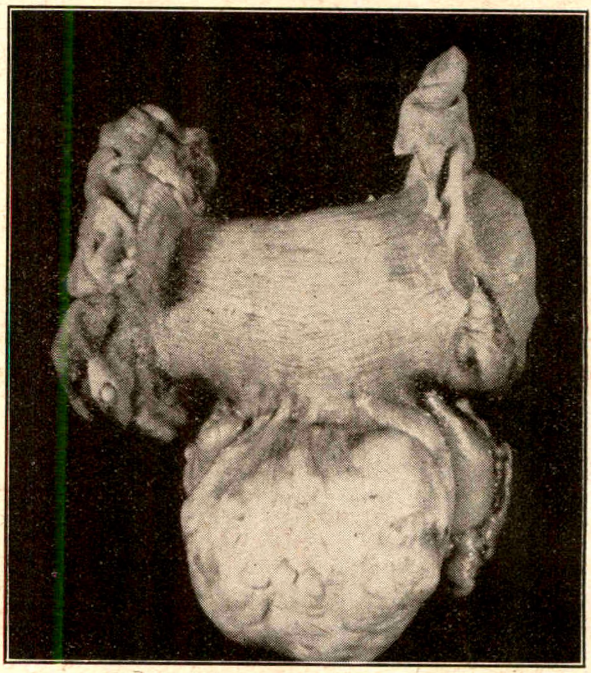

FIG. 2.—The specimen. The diverticulum is on the mesenteric border.

In Nov., 1939, after a particularly severe attack, a new radiological examination was made. Previous *x*-ray examinations of the stomach, duodenum, and gall-bladder had been negative. On this occasion Dr. R. O'Donoghue demonstrated a large jejunal diverticulum (Fig. 1) 18 inches from the gastro-jejunal flexure. There were also several small diverticula in the small intestine. These emptied with the intestine, but the large diverticulum retained the barium for more than 48 hours.

The patient was an obese subject with chronic bronchitis, and the operation had to be postponed owing to her developing bronchopneumonia. After suitable convalescence, laparotomy was performed under local anaesthesia on April 10, 1940. In spite of the many adhesions from the previous laparotomy, the diverticulum, which was on the mesenteric border of the intestine, extending into the mesentery, was easily located. The segment containing the diverticulum was excised and the continuity of the jejunum restored by end-to-end anastomosis, which was reinforced by a free omental graft. The patient made an uninterrupted recovery, and has remained quite free from her former symptoms. She is, in fact, better in health than at any time during the past twenty years.

Examination of the specimen (Fig. 2) showed that the diverticulum was about the size of a tangerine orange. When it was distended with water it held nearly half a pint.

London, W. HAMILTON BAILEY, F.R.C.S.

In an investigation of carbohydrate metabolism in animals reduced to a subacute state of thiamine deficiency, H. A. Harper (*J. biol. Chem.*, 1942, **142**, 239) found that, compared with normal animals, there was a decrease in the rate of absorption of glucose from the intestine. There was also a decrease in the extent of hepatic glycogenesis, as well as in the rate of breakdown of glycogen.

Reviews

TREATMENT AFTER OPERATION

After-treatment. A Guide to General Practitioners, House Officers, Ward Sisters and Dressers in the Care of Patients After Operation. By H. J. B. Atkins, D.M., M.Ch., F.R.C.S. (Pp. 252; illustrated. 15s., plus 7d. postage.) Oxford: Blackwell Scientific Publications.

After-treatment is of paramount importance in determining not only the state of a patient's convalescence and subsequent health, but even his chances of survival. Such treatment is very largely in the hands of those named in the subtitle to this book and, as so much depends upon it, it should be thoroughly understood by them. The book is an excellent account of the recognized methods and should be very welcome at the present time. In addition to the after-treatment of operations it includes that which should follow certain injuries, such as burns, and head injuries producing cerebral concussion or contusion, the management of which may come within the province of those for whom it is primarily intended. Appendices on "Writing Reports" and "Appearing in Court" make valuable additions which are likely to prove especially useful to house-surgeons.

In his account of the after-treatment of head injuries the author regards the revolutionary practices of the Oxford School as too experimental to merit description, but his advice to give half a grain of luminal night and morning for as long as a year after a severe head injury may be regarded by some as a measure no less experimental than any of the practices of the Oxford School. We regret his omission of the treatment of closed head injuries by continued gentle dehydration, but perhaps the most noticeable oversight is the absence of any reference to "tidal drainage" of the bladder, which has recently been shown to be a valuable advance in dealing with the paralysed bladder of spinal cord lesions.

For the most part, however, there is little to criticize. If some of the statements are rather too dogmatic to be entirely and universally acceptable—e.g., that rectal saline after "closed" resections with obstruction is unsuitable because it may aggravate paralytic distension (and there are surgeons who regard proctoclysis as a valuable part of the after-treatment of these very cases)—such dogmatism at least has its value in making clear-cut teaching for readers. The illustrations are good and sufficient in number to enliven the text, which is easily read and printed in clear type, and the whole makes an attractive volume of convenient size. We regard this as a valuable book which will meet a real demand to-day for a concise account of post-operative management. It should make a particular appeal to the practitioners, house-surgeons, and sisters who are left to tide the patient over that critical period—after the surgeon has departed.

BODY MECHANICS

Body Mechanics in Health and Disease. By Joel E. Goldthwait, M.D., F.A.C.S., Lloyd T. Brown, M.D., F.A.C.S., Loring T. Swaim, M.D., John G. Kuhns, M.D., F.A.C.S. With a chapter on the Heart and Circulation as Related to Body Mechanics, by William J. Kerr, M.D., F.A.C.P. Third edition, completely revised and reset. (Pp. 316; 121 figures. 30s.) Philadelphia, London, Montreal: J. B. Lippincott.

This book is an interesting attempt to correlate functional disorders, and even organic disease, with faulty body mechanics. The authors, four of whom are orthopaedic surgeons and one a physician, claim that different anatomical types, such as the slender and the stocky, have a differing susceptibility to disease, and that long-continued persistence in faulty body mechanics may so interfere with the normal physiology of structures and organs as eventually to cause actual organic disease. While the authors do not make any exaggerated claims that organic disease can in every case be cured by correction of mechanical faults and improvement of posture, they quote many cases in which much benefit has resulted from this, even in such conditions as long-standing gastric ulcer, gall-bladder diseases, diabetes, disseminated sclerosis, and polyarthritis. From this it seems obvious that improvement could be much greater if treatment were undertaken earlier, before organic disease was advanced or, preferably, present at all. Prevention is better than cure, and the authors put in a strong plea, with which there will be general agreement, for early detection of postural defects in childhood and their correction by remedial exercises. Treatment is considered in detail and tables are given of the exercises which have been found most useful in practice. The book is well illustrated and a comprehensive bibliography is appended.

The reviewer, who is an orthopaedic surgeon, found himself in substantial agreement with the principles and practice expressed in this book, but it should have a wider appeal to many sections of the profession, particularly perhaps to general practitioners and school medical officers, who have the opportunity of detecting early deviation from the normal, and to physicians charged with the treatment of the "chronic" medical case. It could also with advantage be read by members of the massage profession.

TROPICAL DISEASE

Stitt's Diagnosis, Prevention and Treatment of Tropical Diseases. By Richard P. Strong, M.D., Sc.D., D.S.M., C.B. Sixth edition. (2 volumes. Pp. 1,747; 398 figures; 1 plate. £5 5s. net.) London: H. K. Lewis & Co. 1942.

In these far-travelling days the British medical man will be apt, sooner or later, to find himself in the presence of one or other of the strange diseases of subtropical and tropical lands. To whom then must he turn for help and scientific guidance? There are several textbooks, by well-known British authors, which will appeal to him, and here is one, by an American, with which he ought to be acquainted. Stitt's treatise in two volumes, which weighs like a Service rifle, is not the sort of thing to take into the field, but it contains much that will reward careful study before embarkation. There are few tropical medical subjects—and these are either quite out of the ordinary or very unimportant—which the reader will not find fully discussed.

The reader will learn that there are many anophelines which can transmit malaria, but that only a few are of any practical importance; that anophelines can fly or be carried for miles, but that it is not the long-distance record breaker that causes the real damage; that there are four malaria parasites which are accepted as species, but that *Plasmodium falciparum* is the one to beware of. The malarial diseases are still the gravest medical problem of the Tropics. Their distribution, signs and symptoms, pathology, and treatment are set out in orderly and thorough manner. All the other diseases are discussed in a similar way. There is a reasoned presentation of the facts, supported by evidence from a host of workers on each subject. It is true that the majority of the authorities cited are American, but this is not a matter for surprise. The population of the Americas is very large, and for various reasons the number of persons there who are carrying out research along medical lines is relatively great. Further, there are many tracts of country in which tropical diseases are rife even to-day, so that many American workers have ready access to local material.

The reader of "Stitt" will learn why it is now held that the larvae of the guinea-worm, *Dracunculus medinensis*, do not penetrate the cuticle of *Cyclops* but are ingested by this crustacean, and why *Ascaris* prevalence is considered by many to be a good indicator of the local level of social hygiene. He can find much evidence which shows that yaws is syphilis, and also much which shows that it is not. He will observe that the positive Wassermann reaction, often accepted as entirely specific, is viewed with an increasing scepticism where certain tropical diseases are concerned. He may also observe that Strong finds very confusing the use of such similar names as granuloma inguinale and lymphogranuloma inguinale for two different venereal diseases, and he may well agree with him.

It is significant that Strong, in these volumes, gives a useful amount of space to the various means of prevention of disease. The advances during recent years in the methods of diagnosis and treatment have been great, and there is little doubt that future advances will be greater still. But they are unlikely to lead to a substantial diminution of disease, except in a few cases. One of the most hopeful auguries for the future is the conviction, rapidly growing among medical men, that the abolition of the causes of disease is a matter which lies within their province, and indeed constitutes one of their prime functions. Strong's revision of "Stitt" with its salutary emphasis on the best means of preventing disease is a welcome sign of the times.

Notes on Books

Three volumes of the Oxford Medical Outline Series, on *Abdominal Surgery*, on *Thoracic Surgery*, and on *Surgery of the Head and Neck* respectively, have recently reached us; others of the series have also been published, while still others are in the course of preparation. The object of these volumes (American in origin) appears to be to cover in outline form the chief features of the surgery of the region considered. Developmental, anatomical, and pathological aspects are dealt with, and, as the author of one volume writes, the aim has been to arrange fundamentals in an orderly manner. A number of blank pages interleaved with the text enable the student to expand the outlines thus presented to him. Written by practising surgeons, these volumes give a modern summary of the subjects treated, and if because of their tabulated character, unrelieved by illustrations or diagrams, they make rather too rich and concentrated a diet to be readily assimilated by the general reader, they should at least be valuable as refreshers to senior medical students. They are clearly printed, well tabulated, and of convenient size. While their chief appeal will probably be to the candidate undergoing a coaching course or on the eve of his examination, the coach as well as the coached should find them helpful. The price in this country is 12s. 6d. each volume.

Preparations and Appliances

INSTRUMENTS FOR THE ANEURYSM NEEDLE TECHNIQUE

Mr. HAROLD DODD, Ch.M., F.R.C.S., surgeon to the King George Hospital, Ilford, writes:

The following instruments have been found useful for the aneurysm needle technique of ligaturing blood vessels before dividing them rather than the conventional "clip, cut, and tie," especially in gastric resections, nephrectomies, ligature of the cystic duct, the appendicular mesentery, the thyroid vessels, and for ligature and injection of varicose veins.

A Dissector-director.—Dissectors, directors, and dissector-directors are numerous, and an addition to this many-patterned class must be justified by real usefulness. The instrument illustrated (Fig. 1) is a good length, round-pointed, deeply grooved, and slightly curved at the tip. The generous channelling is its claim to distinction: this enables the aneurysm needle to be passed easily under the tissues without engaging in something below or at the sides, and particularly it permits the blade of the scissors to slide underneath for easy cutting; most directors are too shallow and narrow for this.

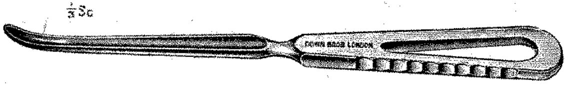

FIG. 1

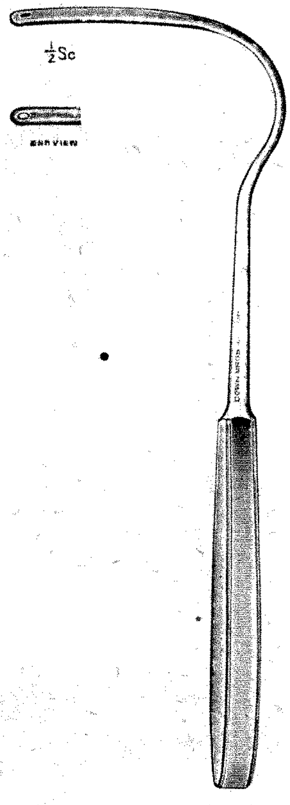

FIG. 2

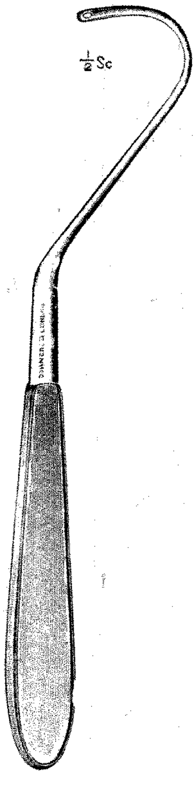

FIG. 3

An Aneurysm Needle.—The aneurysm needle shown in Fig. 2 is characterized by a long beak which enables it to carry a ligature round inaccessible pedicles like the coronary or renal artery, and then to bring it back close to the surface of the wound. Since this instrument has been made it has been found that Mr. Winsbury White had designed a somewhat similar needle for kidney operations.

A Delicate Aneurysm Needle.—This aneurysm needle (Fig. 3) is light in weight and fine in shaft and tip. It is used for passing behind delicate leashes of vessels behind the duodenum.

"*Seeking Forceps.*"—These seeking forceps (Fig. 4) are invaluable for defining the delicate vessels encountered behind the duodenum and about the thyroid gland.

The four instruments described above are made by Messrs. Down Bros.

A Light-weight Needle-holder.—The needle-holder shown in Fig. 5 has been found suitable for the dainty suturing required in plastic operations on the skin, on the kidney pelvis in the child, on the common bile duct, and for nerve and tendon suture. It is characterized by a certain grip of the finest needles, and its agreeably light yet dependable spring. It has an attractive bend of the handles which fits them snugly into the palm of the hand. The way in which it is held is illustrated. It will be found strange at first, but comfortable and efficient after practice. It was made first by Messrs. Vann Bros.

SATURDAY JULY 25 1942

SOCIAL MEDICINE

As was announced last week, it has been decided to establish at Oxford an Institute of Social Medicine and to appoint a professor to be in charge of it. The purposes of the Institute have been set forth as follows:

> To investigate the influence of social, genetic, environmental, and domestic factors on the incidence of human disease and disability.
>
> To seek and promote measures, other than those usually employed in the practice of remedial medicine, for the protection of the individual and of the community against such forces as interfere with the full development and maintenance of man's mental and physical capacity.
>
> If required by the University to do so, to make provision in the Institute for the instruction in Social Medicine of students and practitioners of medicine approved by the Board of the Faculty of Medicine in the University of Oxford.

With the warm approval of Lord Nuffield, the Nuffield Provincial Hospitals Trust has decided to devote £10,000 a year of its income for the next 10 years to the creation of a Professorship of Social Medicine and to the foundation of the Institute in which he will work. The Institute will be managed by an administrative committee on which the Trust will be directly represented by six members. Those who read Sir Farquhar Buzzard's paper in the *Journal* of June 6 probably guessed that this was by no means an arm-chair essay, and that one sentence in particular presaged a new departure in a university which can no longer with justification be described as a "home of lost causes." The sentence was: "We still await the establishment of the first chair and the first department of social medicine in this country."

The broad idea of "social medicine" is of course not new, and it may be interesting to recall here the proposal made in 1908 that the B.M.A. should form a Section of Medical Sociology as one of the Sections of its Annual Meetings. The promoter of this was the late Dr. E. R. Fothergill. Supporting him was Dr. Alfred Cox, then representing Consett, Gateshead, and subsequently Medical Secretary of the Association, and happily still alive and active. Dr. Cox's words, as reported, are strangely apposite now, 34 years later. "If there was one thing," he said, "more apparent than another in the present day, it was the vast interest that the State was taking in the affairs of the every-day citizen, and it was quite certain that much proposed legislation could not be carried out without the assistance of the profession." It is interesting, too, to recall that one representative wanted to know whether "Sociology" meant "Socialism."

The move now made by Oxford is the end-point of a series of reactions that have been taking place in the medical test-tube for some time now. And it is also the beginning of a new series of reactions the end of which it is difficult to foresee. That the change has been heralded by one who has had a distinguished career in clinical medicine is itself significant. This imaginative move has not had its origin in the public health service or in the Government Department officially concerned with "health." It has as its common origin an ancient university and a wealthy industrialist. This, too, is significant. The new Institute of Social Medicine will incorporate in itself much that was inchoate in the minds of practising doctors, and will become the focus of the aspirations of those far-seeing medical men who have for long realized that the stethoscope, the bottle of medicine, and the scalpel represent in essence the failure of Medicine to get to the roots of illness. Sociologists have themselves often been criticized for neglecting the individual and concentrating too much and too long on the group and on mass reactions of human beings. Medical men have perhaps erred in the opposite direction by giving too exclusive an attention to the individual patient. But Medicine has, we believe, set about its task in the right way—the way of the biologist who must observe, collect, and classify. There is a regrettable tendency nowadays to belittle the clinician. Yet it is because the clinician has for centuries kept to the fundamental scientific discipline of observing and, where possible, measuring, that facts are now available to be observed in their interrelations by the statistician and the epidemiologist. And let it not be forgotten that the sanitarian and the epidemiologist are helpless without the clinician to recognize the disease in the first place, and the laboratory worker to confirm and refine the diagnosis in the second. The clinician must himself now learn to see health and disease through the eyes of the public health worker, must see the sick person as a unit in society worked upon by a multiplicity of physical and psychological circumstances. He must become more aware of the lesson stressed at Peckham—that the family is the health unit. All this will not happen to-day or even to-morrow, for the change in medical thought that is taking place and seeking expression in action does not find a medical profession educated to take the fullest possible part in "Social Medicine." Nor is the curriculum yet planned so to mould the medical student's mind that it will adapt itself to the new medical world that is slowly taking shape. We may even wonder whether enough of those who teach the student have minds elastic enough to stretch to new conceptions.

In a leading article entitled "Social Factors in Medicine" last year[1] we observed that few individual men had had more influence on the public health movement in the 19th century than John Snow, and that he had been "less concerned with propaganda than with proving by scientific inquiry that cholera was a water-borne disease." There is always the danger that doctors will approach medico-social issues with propagandist aims that are not strictly medical in origin. There is, too, the danger that doctors will go still further in usurping the place of the priest in society through a flush of humanitarian feeling, and that the medical profession will return to its beginnings in the temples of Aesculapius. It is the men like John Snow, who in their professional life stick close to fact and inquiry, that bring about the big changes that make for social betterment—an end which every good doctor must wish for.

TUBERCULIN PATCH TEST

The intradermal injection of tuberculin, as used in the Mantoux test, has provided much valuable information on the incidence of tuberculosis in large groups of people; its value to the practitioner is perhaps not as widely recognized as it merits. The basal data are available in the classic investigation by D'Arcy Hart.[2] He tested 1,030 clinically tuberculous patients with the routine Mantoux dose, 0.1 c.cm. of 1 in 1,000 old tuberculin, and obtained 96% of positive reactions. Among the clinically non-tuberculous at early ages the readings were mostly negative: 93.5% negative among 121 children aged 0–2, 83% among 124 aged 3–5, and 69.5% among 245 aged 6–10. The Mantoux result is clearly of much significance at early ages. Furculow,[3] in a valuable study in the U.S.A., used the "purest" tuberculin available, the Seibert P.P.D., and obtained the same type of result: 99% of 468 adults with clinical tuberculosis gave a positive Mantoux result, while less than 10% of 309 young people aged 6–9, with no clinical signs or known history of contact with tuberculosis, gave a positive reading. Bradshaw[4] feels that the diagnostic value of the test is underrated. At the Great Ormond Street Children's Hospital between 1934 and 1938 he tested 3,010 children referred by the clinicians: in 748 the test was positive. One important point was that in the examination of "wasters, contacts, adenitis and arthritis suspects" the test enabled three-quarters of the "suspects" under 4 to be cleared of suspicion of tuberculous infection; even in the 10–12 group half could be cleared. Bradshaw regarded the test as not devoid of some risk of reaction in erythema nodosum and phlyctenular conjunctivitis. In adult life the test is not so generally useful, for few who live in cities escape contact with the tubercle bacillus. Most recover but thereafter give a positive Mantoux response. Of 134 clinically non-tuberculous adults tested by D'Arcy Hart 88% were positive to the routine Mantoux dose. The positive percentage differs in different populations, and with the decreasing incidence of tuberculosis up to the beginning of the war the Mantoux rate was probably falling. New York City in 1921–8 showed a positive rate for age group 12–13 of 45.5%, whereas in 1934 the rate had dropped to 35.2. If the incidence of tuberculosis in the general population is low, adults who are negative to the Mantoux test will be more numerous and a negative Mantoux response will be of significant help to the physician, as was pointed out by M. P. Crowe.[5] Together with a low erythrocyte sedimentation rate it will justify a reasonably confident decision that baffling symptoms in a patient are not due to an active tuberculous infection.

---

[1] *British Medical Journal*, 1941, 1, 715.

[2] Med. Res. Cncl. Spec. Rep. Ser., 164, 1932, London.

Invaluable as the intradermal test is, the method has drawbacks. The dilution of tuberculin to be used will keep for only a short time; the needle prick, though not bothering adults, may cause tears in children; finally, tuberculin adheres so tenaciously to glass that a special syringe must be kept for the test, and indeed for each dilution. In the presence of suggestive symptoms the medical man cannot accept a negative Mantoux result, but must know if his patient falls in the extra group of 7% inculpated by tests with the stronger dilutions 1 in 100 and 1 in 10. In order to avoid some of these difficulties Grozin[6] in 1933 let fall a few drops of tuberculin on to adhesive plaster, which was then applied to the skin of the patient. He called the method "the patch test." Vollmer[7] improved it by saturating filter paper with undiluted tuberculin, drying it, and attaching it to the adhesive side of the plaster. He has devoted much attention to the test, and has reported[8] on 2,900 patients, of whom approximately 720 were tuberculous. In 98% the results of the Mantoux and patch tests agreed. A number of recent papers, notably in America and Australia, testify to wide interest in the patch test. Reismann and Grozin[9] in New York State examined 1,000 patients by the Mantoux and the patch method: 49 were positive to both tests, 3 responded only to the Mantoux, and 2 to the patch test only. Furculow tested 612 patients aged 6–19: 123 were positive to the Mantoux test. The patch test missed 6.7% detected by the Mantoux test, and in 7.4% gave a positive where the Mantoux test failed. Though a few writers have described much larger discrepancies,[10] the majority of reports indicate that the patch test will give the right answer in about 95% to 98% of young patients. It appears to be less trustworthy in adults, for whom the Mantoux test seems preferable.

In descriptions of discrepancies many points of interest have been noted. All tests of the kind have a basal small error. Even when the same dose was injected from the same syringe intracutaneously into the two arms of the same patient, the results in the two arms differed in 3%. Different brands of tuberculin have given different percentages in tests on the same patient. Savage[11] in the U.S.A. recorded 60% and 47.6% in duplicate Mantoux tests with two commercial tuberculins. Even two small pieces of filter paper under the adhesive plaster at adjoining spots have on rare occasions given one a positive and the other a negative reading. Error has arisen from the application of the patch to skin that has been exposed to much sun and wind, or from failure to remove all grease from the skin with ether, acetone, or benzene before applying the patch. Again, different workers have used different tuberculins, O.T. or P.P.D. Colebatch[12] has also described false negatives due to the deterioration of patches during transit. When all these points are borne in mind, and when the practitioner can be satisfied that he has at his disposal a standardized uniform "patch," the test will probably prove of considerable value to anyone who is impelled by the exigencies of practice to sacrifice the greater accuracy of the Mantoux test to the convenience of the patch test. While a positive reading may be accepted, it is wise to accept a negative one only provisionally, subject to the result of a Mantoux test with the second dose, 0.1 c.cm. of 1 in 100 tuberculin. If the Mantoux test is not being as much used in general practice as it should be—and evidence points that way—the use of a properly standardized patch will be preferable to no test at all

DIARRHOEA AND VOMITING

The fact that the "peak" occurrence of diarrhoea in the summer months presents nothing like the tragic problem of twenty-five years ago has perhaps led to some neglect of the study of the curious relation between hot weather and this alarming metabolic disturbance of the young. It is commonly taught that summer diarrhoea has been abolished because of three main factors: the educational work of the infant welfare centre, the increased use of dried milk, and the disappearance of manure-covered streets with the advent of the motor car. These factors all presuppose an infective origin of the condition, but it was never clearly established that even the minority of cases were due to recognized pathogenic organisms. Recent work has suggested that a virus ought to be considered, but the fact that diarrhoea still occurs more frequently in warm weather, despite all the improvements in hygiene, suggests that heat might act in some ways other than by favouring the growth and distribution of some infective agents. Just before the war R. M. Campbell and A. A. Cunningham[13] studied a group of 574 infants with diarrhoea and vomiting admitted to the Park Hospital, London County Council. Grouping the cases by the month of the onset of symptoms, they found the largest number of cases to occur in July and September, and the smallest in January. More than half the cases admitted had occurred in the five months June to October. As gastro-enteritis may be a disease of mixed causations, it might be thought that the seasonal incidence of any series of cases would be the result of the interplay of a variety of infections of different epidemic constitutions. All cases without any evidence of parenteral infection (bronchitis, pneumonia, otitis, urinary infections, and so forth) early in the illness were analysed in the same way for monthly incidence, but the results were essentially the same, and the warmer months yielded an undue proportion of cases. Of the whole series there was evidence on admission of parenteral infection in less than one-third of the total number, and, taking the series as a whole, parenteral infection had no apparent effect upon the general death rate, which was 27.7% for the whole series. A distinction between dehydrated and non-dehydrated cases not only indicates the chief danger of diarrhoea and vomiting for the young but gives the clue to treatment and perhaps to causation. The mortality for the dehydrated group was 53.7% and for the non-dehydrated only 2.4%. It is small wonder that the authors summarize therapy by stating, "Whilst the general nursing management must be of a high order . . . the most important single factor in treatment is the relief of dehydration." For dealing with dehydration the authors favour the continuous subcutaneous route, ringing the changes on normal saline, Ringer's solution, and 3% glucose in 0.25% saline. In seriously ill patients this is supplemented in the first twenty-four hours by intraperitoneal and intravenous therapy. The profound disturbance in cellular chemistry set up by a negative water balance is probably not yet sufficiently appreciated. Recent biochemical studies have shown how serious this may be, and Campbell and Cunningham promise a further paper on water and salt metabolism. Meanwhile the effect of hot weather in facilitating fluid loss might be borne in mind as a possible factor in turning a mild gastro-enteritis into a deadly biochemical disturbance. Breast-feeding as a preventive measure can once again be supported by the Park Hospital figures. In the whole series only 4.5% of the infants were breast-fed at the time of onset, and only 3 out of the 18 died. About four-fifths of the infants contracted the disease at home, and it would appear that extra fluid (plain boiled water or even weak saline) might be a useful measure of prophylaxis for all babies, however fed, in hot weather.

A NATIONAL AMBULANCE SERVICE

Hospital regionalization when it comes about will presumably carry with it regionalization of the ambulance service, for the ambulance, its promptitude, its equipment, and the skill of its attendants, may be as important in life-saving as the hospital bed itself. Ambulance provision is now probably, in bulk, not inadequate, but it needs co-ordination to avoid overlapping on the one hand and delay on the other and to overcome those difficulties which occasionally arise when there is doubt as to which authority is responsible for providing transport. The ambulance is now such a familiar vehicle that it is hard to believe, as we are told in a booklet issued by the Home Service Ambulance Commitee of the Joint Council of the Order of St. John and the British Red Cross Society, that before 1914 the civil population of England had practically no ambulance service. Many will remember the hand-propelled litter in charge of the police; in a provincial town of 20,000 population the other day we saw one of these in service after an accident. The last war gave a great impetus to ambulance organization, and at its end a number of people, under the auspices of the Joint Council, resolved to carry wartime experience into civil life by providing a range of ambulance stations throughout England and Wales. This Home Service Ambulance, which is by far the largest single ambulance organization, has 136 stations, and 320 others are affiliated, and last year it carried nearly 200,000 patients. In Scotland the St. Andrew's Association has over 100 ambulances, 23 of them in Glasgow. In addition there are the services of the local authorities, and London and other authorities have excellent ambulance fleets. Many hospital contributory schemes provide transport facilities for their members, many hospitals run their own ambulances, and, finally, there is the A.R.P. service, largely of improvised vehicles. The need for an adequate regional and divisional organization of standard vehicles and stretchers is apparent. Standardization is important if there is to be free interchange. In its 23rd annual report the Home Service Ambulance Committee points out that ambulances accommodating only a 6-ft. stretcher will be a great disadvantage in a widespread post-war interhospital scheme, and urges all ambulance builders, looking to the future, to build or modify their vehicles to accommodate the 7 ft. 9 in. stretcher. No doubt also the term "ambulance" will increasingly connote first aid as well as transport, and at convenient centres in each region there will be a first-aid ambulance unit with resuscitation and blood-transfusion apparatus. The committee already maintains such units in large industrial and in certain coastal and mining areas. In the recasting of the hospital system of the country a well-coordinated ambulance provision will not be the least of the essentials.

"LEKARZ WOJSKOWY"

Just one year ago the Polish Army Medical Corps published the first number of its journal, *Lekarz Wojskowy*, in this country. We have recently received the February-March-April issue for this year, and it bears adequate testimony to the energy of the editor and to the skill and knowledge of the contributors to what is, in these days, quite a substantial number. There are, for example, articles by Dr. Bohdan Hejduk on the organization of field surgery in modern war; by Prof. Antoni Jurasz, who is Dean of the Polish Medical School in Edinburgh, on considerations on surgical shock; by Dr. J. Skladal on the principles of physical diagnosis of latent and preclinical lesions of the lungs; and by Dr. A. Fidler on the theory of true uraemia. There is, too, a report of the congress of the Polish and Czechoslovak doctors held in Edinburgh in September of last year. Most of the articles are in Polish, but there are good summaries in English which will enable the English reader to get some idea of the work and views of the doctors of the great Slav nation which has been our close ally since September, 1939.

DOCUMENTARY REPRODUCTION

Micro-film processes for automatically recording documents have received much attention, particularly in America, during the last 5 or 8 years, and now in this country they have come into prominence through the risk of destruction of original documents by enemy action. Legal and banking documents are now being copied regularly and conveniently by the camera, and libraries are making large use of the facilities offered by the new developments in photographic technique. Much of this work is done with miniature cameras, often by 35-mm. cinematograph cameras taking pictures 18 x 24 mm. A thousand pages can be recorded in this way on a film spool measuring 3¼ x 1¼ in. Sixteen pages of a scientific paper, for example, will go on one foot of film. As for the time taken by micro-film copying, we learn that in Bermondsey 500 folios of parish registers were recently photographed in a few hours, a work which, if undertaken by hand, would have occupied months. The recording apparatus is a camera embodying a lens system giving high-quality definition over a wide field of view. The viewing or projecting apparatus is of different kinds. A hand viewer is necessary for the rapid recognition of titles of documents; this needs a lens magnifying perhaps no more than seven times. Then there should be a table viewer for reading the image while the reader sits with an illuminant so arranged that the room need not be in complete darkness; here the magnification may be twenty times. Another form of viewer may be used for projecting the image over a typist's shoulder on to a small screen when the document has to be recopied. The difficulty has been hitherto the expensiveness and complication of much of this apparatus. Recently Mr. B. K. Johnson, a teacher at the Imperial College of Science, showed to the Optical Group of the Physical Society a range of simple instruments constructed by him, which, we understand, are about to be manufactured by a commercial firm. The camera in the recording apparatus can be used at a low aperture, such as F/8, but the average grain size of the film now produced is just about equal to the resolving power of a camera lens working at the wider aperture of F/4.5. Part of the simplicity of Mr. Johnson's devices is due to the realization that most of the documents to be copied are of quarto or at least not larger than foolscap size, so that, accepting this limitation, one can do away with any automatic mechanism for moving the camera lens. A device is incorporated for moving the film along for the correct distance for each exposure. A different plan is pursued at the National Institute of Medical Research, which has been interesting itself in the micro-film process for recording papers from journals for storage in its library. Here it has been found that for simplicity of working a small repeating back camera, using flat film, is preferable to an arrangement for the use of roll film, with its gates and sprockets; the flat film is moved by a small lever. These methods of documentary reproduction are still in the stage of infancy, and the future will no doubt see great developments. The recent introduction of a new sensitive material (micro-negative copying film, panchromatic) is a further step towards the accurate registering of minute detail. With modern high-resolution films it is by no means impossible to copy a page of a daily newspaper containing small advertisements in such a way that every word is clearly readable; this is customarily done with the double frame size of picture measuring 24 × 36 mm. It may be added that micro-film is now being largely used also for taking enlarged photographs of microscopical preparations at low magnification.

TOWARDS THE CLEAN CITY

In the vast dreamland of social reconstruction, the contours of which are only dimly seen, all sorts of movements, admirable and less admirable, are staking out their claims, and they are right to do so because, in spite of the indeterminate nature of the ground, the "concessions" will probably go to those who are there first. A body early in the field is the National Smoke Abatement Society, which has prepared a memorandum entitled *Smoke Prevention in Relation to Initial Post-war Reconstruction.* The memorandum leaves out of account long-term proposals and concerns itself only with the ways in which smoke can be prevented in the new buildings which will begin to arise all over the country when the war is over. So far as these are commercial buildings, it is thought that by requiring all new installations of fuel-burning equipment to receive approval of a special authority, by banning open fires, and by making obligatory the use of smokeless fuel, a clean atmosphere could be achieved in the blocks of shops and offices which make up the centre of a modern city. For industrial plant there must be control of new installations and in many cases also of use and maintenance. It is the multitude of domestic chimneys which will always be the difficulty. But here again the construction of new houses depending entirely upon gas and electricity might be encouraged, and even though one open fire per house be conceded, the grates can be so designed as to use smokeless fuel. The memorandum urges that there should be smokeless central zones in cities, so that the shopping and promenade streets and the central parks and gardens may be pleasant, cleanly places instead of places of greyness and grime as they are now. Indeed, there might come about a state of affairs in which the central part of a great city, instead of enjoying only half the amount of sunlight which is the portion of the outer suburbs, would be brighter and sunnier than they. The same society has issued a pamphlet entitled *No Clean City,* in which smoke is shown, by telling quotations and still more telling photographs, to be the enemy of health and amenity. We notice one quotation by the M.O.H. for Manchester: "The abolition of smoke from our midst would do as much for the improvement of public and individual health in our industrial centres as any other single action open to this country."

PHOTOGRAPHING ANTIBODY ACTION

There is much in microbiology which can only be deduced, since it cannot be seen, and the limits of what can be achieved by direct observation were thought to have been reached when Barnard perfected photography by ultraviolet light. A long step further has been taken by the introduction of the electron microscope, and the possible uses of this instrument in biology are now beginning to be explored. Some idea of what it may achieve can be gained from a paper by S. Mudd and T. F. Anderson,[1] which is illustrated by photographs showing the action of antiserum on bacteria. They were taken at a magnification of 8,000 diameters and printed at one of 25,000. These sensational pictures show monstrous bacilli with long and exceedingly fine flagella. Their first usefulness is, indeed, in showing that flagella are much thinner than stained preparations would lead anyone to believe, the estimated thickness of a flagellum of *Bact. typhosum,* for instance, being only about 290 A.U. Admixture with homologous serum—heterologous having no such effect—causes both changes in the bacterial cell wall and a measurable increase in the thickness of the flagellum, attributable to deposition of antibody molecules on its surface. It is known that the antibody globulin molecule is elongate, and from its known dimensions and the measurements here made it could be concluded that the molecule was lying flat on the surface of the flagellum. By deduction not only from these observations but from work by others these authors conclude tentatively that in a low concentration of antibody patchy deposition takes place with the molecule lying parallel with the surface; with somewhat higher concentrations molecules so disposed form a continuous film, but in higher concentrations still a radial disposition is assumed. Another point vividly illustrated is that flagella sensitized by antibody attract particles of other kinds. When the serum used contained a precipitate, this was adsorbed on the surface of the bacterial cell and its flagella, with the result that they are entangled in large irregular masses of granular material. But these photographs are chiefly of interest as a portent: clear pictures at such a magnification afford an almost unlimited prospect for new observations.

SAVING COTTON-WOOL AND USING SAWDUST

BY

DUNCAN C. L. FITZWILLIAMS, Ch.M., F.R.C.S.

Among the schemes brought forward by the different professions for saving shipping space, it is strange that the medical profession should have overlooked one that could be very effective. It is the saving which might be made in the use of cotton-wool. Cotton-wool is a light and therefore bulky commodity and must take up considerable space. As it is grown chiefly in America, it must be imported, either in the raw state or as the finished article. An enormous quantity is used in hospitals, surgical centres, surgeries, and for many purposes throughout the country.

Cotton-wool has two great qualities for which it is used in surgery. First, it diffuses the pressure of bandages, splints, and apparatus over certain areas of the body. Fat people, therefore, scarcely require any of this "padding," as their own fat carries out this function, but wont and custom dictate that we should apply rather more to them than to thin people, because they are larger and have a greater surface. Splints used to be padded with cotton-wool, but with the application of plaster to fractures this is no longer necessary; and our results are better, as the apparatus does not slip out of position, showing that it was largely custom which dictated the use of cotton-wool. Fomentations are always covered with large quantities of cotton-wool, which is thrown away when the fomentation is removed, but a folded soft towel is just as good and can be applied again and again.

The second reason for the use of cotton-wool is its absorbent qualities for septic wounds or where there is discharge, but how many septic wounds do we see to-day? If we consider why we apply huge quantities of wool over a simple appendix wound we shall find that we do so because the theatre sister hands it to us. If it must be used the quantity might well be cut down to one-quarter. The same thing could be said of nearly all clean operations.

Enormous saving could be made in the dressing of clean wounds; often the whole dressing is discarded, and a big wodge of cotton-wool applied over a new one, even when the wound is already practically healed. If there is any need for wool over a fresh wound, there can be little need for it when the wound is nearly healed. Some saving might also be made in the amount of gauze used. This saving of shipping space can only be brought about by the thoughtful co-operation of the surgeon, the assistant or house-surgeon, and the sister or nurse, chiefly the sister, as she can control the nurse and the amount the surgeon applies; but it should be remembered there is no more conservative body of people than hospital sisters. The surgeon would do well to give orders on the subject.

Dressings from Sawdust

Some time ago the B.B.C. broadcast a request for suggestions for the use of sawdust. Perhaps the following experience might prove useful, for my brother and I managed a hospital of 100 beds in Rumania during the last war for many months without any dressings at all except sawdust, and a better dressing could not be asked for. We had no surgical equipment except our pocket surgical cases and the housewife of the matron; this may sound romantic, but was nevertheless a fact. How the other needs were supplied makes interesting reading, but cannot be gone into now. I will deal only with the sawdust dressings.

We had nothing except an ambulance; the buildings and bedding were of course supplied. The shops throughout Rumania were supposed to be completely denuded of material of every kind, but it was found that material could be produced when it was learned that we belonged to the British Red Cross, and it spoke volumes for the reputation and credit of this country that we obtained what we wanted, although we had little money and could only give "chits." All the shopkeepers were Jewish, and most of their goods had been sold to the Germans before they came into the war. What was left had been commandeered, and there was little chance of their being paid for it. Small wonder, then, that we were right when we thought that there might be something hidden away if we could get at it. Through an accommodating person we bought all the linen, gauze, and muslin we wanted, and smuggled it into the ambulance.

Next a meeting of lady volunteers was called, and their help and their sewing-machines were asked for. They had nothing: we had even to supply the thread; but they were set to work to make linen or muslin bags of different sizes. The material was torn into various lengths and widths and then folded over so that only three sides needed sewing. Coarse black thread was used because it showed up against the white material. One-quarter of the last side was left unsewn and open.

Preparing the Sawdust

We arranged for cartloads of sawdust to be delivered from the saw mills, which abound throughout Rumania, and dumped on clean sheets laid on the floor of a previously cleaned shed. It was then put through a large sieve, which removed all the coarse pieces of wood mixed with it. These were thrown away, and the remainder was sifted well through moderately fine sieves; this process was repeated twice so that all the fine dust was removed. The sawdust from these mills consists partly of real fine dust and the rest is crushed wood in the proportion (speaking from memory) of about one of the former to three or four parts of the latter. It was important to remove as much dust as possible to prevent it getting into the wound, so this fine sieving was done very thoroughly twice.

What was left was a coarse granular substance consisting of crushed wood pulp torn from the interior of the tree trunks by the great broad teeth of the circular and band saws. Considering its source I should imagine that the amount of septic organisms in it was very small. This granular substance was put into the bags through a funnel, until the bag was between one-third and one-half full. The opening in the bag was then sewn up with thick coloured thread, usually red, in such a manner that when the bag had to be emptied, all we had to do was pull the knot at the beginning and the thread came out, thus restoring the opening. The bag was then shaken, turned inside out, washed and boiled, and used again.

The bags varied from about 6 in. by 4 in. for small wounds to 12 in. by 10 in. for large ones or those with much discharge like empyemata. Most of the wounds were horribly septic and discharged freely, and this coarse granular material proved to be highly absorbent. The sawdust swelled as it got wet, so that the pads were always larger when removed than when first applied; hence it was necessary that they should be only one-third to one-half full.

In our improvised hospital the bags were put in tins in the oven, and people were assured they were sterile. Whether this was true or not I do not know; they were never tested bacteriologically, but they were all we had. Layers of material, which had been sterilized by boiling, were first applied to the wounds, and then the bag of appropriate size was added, and the whole fastened in place with improvised bandages. There were no other dressings of any sort, but the hospital was filled to capacity.

I can vouch for the fact that we came to regard these dressings as almost ideal for their simplicity and effectiveness, and we only relinquished them with regret. The credit for the idea should be given to that extraordinarily inventive genius Charles Cathcart, F.R.C.S., of Edinburgh, who mentioned the possible use of sawdust in surgery in an article either in the *British Medical Journal* or the *Lancet* before the last war. I had read this article with great interest; probably it would pay others to look it up.

Since 1932 a specific dietary disease of silver foxes has been recognized as one of the important problems of the fur industry. Its pathological characteristics are similar to those of Wernicke's disease or haemorrhagic polio-encephalitis in man. In foxes the disease is called Chastek paralysis, and it first appeared among the animals on the Chastek fur farm in Minnesota, where in one month it killed one-third of the entire ranch population of more than 200 foxes. Apparently the disease appears among foxes when 10% or more of certain types of fresh whole fish are included in the ration, and it can be prevented by adding large amounts of thiamine. Necropsy reveals severe damage to the liver. The brain lesions are bilat symmetrical, and occur in the grey matter, especially in ventricular region.

Nova et Vetera

MICE IN PLAGUE PICTURES

The identity of the pestilence that destroyed upwards of 50,000 of the Philistines (I Samuel, v) has long been the subject of speculation. It was characterized by the presence of visible swellings in the body, which the translators of the Authorized Version called "emerods"—an archaic word for haemorrhoids. Clearly these scholars did not identify the epidemic as bubonic plague, else instead of the curious word "emerod" they would have used "botch" or "bubo," familiar words in their day. Most interesting, however, is the conjunction of pestilence and emerods with "mice that mar the land"; these malevolent rodents may equally well have been rats.

In a recent paper Otto Neustatter[1] recounts his study of early illustrated scriptural texts, undertaken to determine if in Europe there was any appreciation of the aetiological role of rodents in plague. From a series of such texts—beginning with a Paris MS. of 1250, and including the famous Lübeck Bible—he reproduces representations of the plague of the Philistines in which rats or mice are shown. In all these illustrations, however, the rodents are depicted as scampering round in fine fettle or preying contentedly on the corpses, and there is no indication of any mortality or sickness among them. The Biblical narrative mentions rodents, and in faithful adherence to this the artists introduced them into their pictures without any realization of their special significance. Neustatter seems to doubt the identification of this pestilence as bubonic plague. To my mind there can be no question. Bubonic plague is the only killing epidemic disease characterized by visible swellings—call them emerods or what you will.

It is interesting to consider what was known in this country of the aetiology of plague while the disease prevailed. A mortality among animals was long known to presage and accompany plague in man, but the only association believed to exist between the epizootic and the epidemic was their origin from one source common to both—namely, a plague poison fermenting in the ground. Rats are not stressed, and indeed they are often omitted from the lists of animals affected by plague. Gilbert Skene considered it very ominous when the "Moudewarp [mole] and Serpent leavis the Eird [earth] beand [being] molestit be the vapore contenit within the bowells of the samin [same]." "Serpent" in his day might mean almost any creatures that crawl, from crocodiles to bees. Bacot, who succeeded in infecting hen-fleas with plague, suggested that the occurrence of the disease in these birds would involve grave risk to man. What Bacot suggested Skene appears to have observed 400 years earlier, for he points out that this "infectioun bringis baith man and beast to death . . . and speciallie quhan [when] the Domesticall foulis becummis pestilentiale it is ane sign of maist dangerous pest to follow."

The only animal regarded in England as an active vector of plague to man was the dog, not by contracting the disease but by harbouring infection in the hair. This animal is resistant to plague, and the dog-flea, though a potential vector, in my experience does not bite man readily. On a number of occasions, however, when fleaing dogs, I have recovered from a single animal several dozen fleas not native to the dog, and effective carriers of plague. Dogs, therefore, may readily have picked up and brought home vagrant infected fleas which had abandoned their dead rat-hosts; the exertions of dog-killers in London plagues may not have been altogether misdirected.

The theory of the ferment origin of plague retained official recognition while the disease continued in England, but during the last epidemic in London in 1665 a considerable minority rejected this assumption and contended that the disease is caused by some "animated Matter" which invades the body and produces a poison there. Nathaniel Hodges set himself to investigate this new theory. In one instance only, he reported, was the presence of "animated Matter" demonstrated in a victim of plague. This patient "in vomiting threw up a strange figured Insect; which appeared very fierce, and even assaulted such as were busie to observe it, whereupon it was crushed by a rude Hand, so that its shape is not very discernible." And here ended for a long space the theory of "animated Matter" as the cause of infective disease.

W. P. MacArthur.

Reports of Societies

CHEMOTHERAPY OF INTESTINAL INFECTIONS

At a meeting of the Section of Therapeutics and Pharmacology of the Royal Society of Medicine on June 9, Dr. R. D. Lawrence presiding, Dr. Robert Cruickshank opened a discussion on "The Chemotherapy of Intestinal Infections."

Dr. Cruickshank said that in this field the bacteriological cure was as important for the community as the clinical cure for the individual. Until a year ago the treatment of intestinal infections with drugs had been a complete failure. Typhoid fever was a disappearing disease, but paratyphoid had become a mild prevalent infection. Flexner dysentery was still common in certain institutions. Gastro-enteritis was still a major problem in paediatrics. The sulphonamides had raised hopes, but there were two main objections to these and other drugs: it was impossible to get much practical clue to the value of a drug from test-tube or animal experiments, and the ordinary sulphonamides were readily absorbed from the gut and did not stay to attack the organism in the bowel itself.

The great advance in this field came when Marshall and his colleagues at Baltimore discovered a drug which, while active in the test-tube, yet was not absorbed to any extent from the intestinal tract. The toxic effects of this drug, sulphaguanidine, were minimal. The standard dose with sulphaguanidine was 3 g. three times a day for three days, followed by 3 g. twice a day for a further four days, the week's course thus giving a total of 51 g. In dysentery infections more particularly it was important to give the drug in large doses at infrequent intervals. There was no evidence that sulphaguanidine was of any benefit clinically or bacteriologically in enteric fever, or that any of the sulphonamides were of value in the treatment of the chronic typhoid carrier. Another substance used in the treatment of the chronic carrier—namely, iodophthalein—had a definite bactericidal effect on the coli-typhoid group, and occasional cases of cure had been reported. Sulphaguanidine could cure the convalescent Flexner dysentery carrier and was of great value in the clinical cure of dysentery. In the milder Sonne dysentery the effects were not quite so striking. The Sonne bacillus was a much more hardy organism. In gastro-enteritis sulphaguanidine had given no response. As to ulcerative colitis, he had collected records of 10 cases treated with this drug: 2 showed complete remission after a course, 1 showed improvement, and 7 were unaffected. In dysentery the drug of choice was not emetine, but bismuth iodide and quinoxyl, and for giardiasis there was atebrin.

Sir Philip Manson-Bahr said that there were about as many remedies advanced for ulcerative colitis as there were causes suggested for its aetiology. He had tried sulphaguanidine in 10 severe cases of ulcerative colitis. Given by the mouth it seemed to be no good at all, but if there was a regional ulcerative colitis which could be seen by the sigmoidoscope or radioscopy to be confined to the lower part of the sigmoid or rectum, and the drug was introduced directly on to the mucous membrane, the result might be quite favourable. The best improvement in the cases he had seen was shown in those which contained streptococci in the stools. The drug must be introduced by enema retention and in large doses (7 to 10 g. dissolved in 7 oz. of water and suspended with mucilage or gum of acacia). First of all he gave some emollient sedative like bismuth subgallate in olive oil to soothe the mucous membrane, and then gave the sulphaguanidine by rectal enema, preceded by luminal or small doses of morphine. He could record 4 cases in which there had been remissions up to date for 6 months The drug was altogether retained, not voided. One woman had been ill for 5 years and had had blood transfusion in several London hospitals. Since treatment the stools had become normal. Her haemoglobin had gone up from 50 to 80%, and she was looking and feeling well. Of all the substances he had tried, this had given him by far the best satisfaction.

Speaking of amoebic dysentery, he said that emetine was probably the most wonderful specific in the *Pharmacopoeia*, but it had been badly abused. It had been too often assumed that, because the parasite was knocked out, the disease was knocked out also. Formerly emetine bismuth iodide was given in far too big doses. He now gave 18 to 20 gr. in total—2 gr. at night for 10 nights—and even that was too much. The patient should be given a liberal lunch but no other food for 3½ hours before the drug was given. The giving of the drug should be preceded by luminal in two doses—1 gr. an hour before administration and 1/2 gr. half an hour before. The emetine bismuth iodide should be given in hard gelatin capsules. It had become the popular thing in the Tropics—for example, Kenya—to put everything down to amoebic dysentery and to give periodic minimal injections of emetine. If this were done, even if the case was one of amoebic dysentery, there was a danger of getting an emetine-fast organism. He concluded with a word about giardiasis. The giardia was a mildly pathogenic parasite. If it occurred in enormous numbers in the small intestine it gave rise to a mucoid diarrhoea, and if there was a massive infection a steatorrhoea made its appearance. With the drug atebrin (mepacrine hydrochloride) the specific nature of the treatment could be estimated from the fat content and appearance of the stools.

Dr. HELEN MACKAY said that in her experience of sulphaguanidine it appeared to have no effect in dealing with the severe type of enteritis, but she pointed out the value of chemotherapy in infections associated with enteritis. Until these new drugs came forward, cases of enteritis which had an associated infection, such as pneumonia, were regarded as invariably fatal, but that was no longer true.

In reply to a question Dr. CRUICKSHANK said that he believed sulphaguanidine was marketed by two drug houses in this country and that supplies were available beyond what was required for the Forces.

ULCERATIVE COLITIS

At a meeting of the Manchester Medical Society on May 6 Mr. PETER G. MCEVEDY opened a discussion on ulcerative colitis. There was, he said, much that was not known about this condition, the diagnosis being often incomplete and the death rate high. Basing his remarks on 71 cases that had been under his care in the last 5 years, he showed that, with a more complete anatomical and pathological diagnosis and more active treatment, the mortality could be greatly reduced and the number of complete cures increased. Anatomically, the disease started in the rectum, and commonly spread to involve the whole colon, but rarely the lower end of the ileum. It was an inflammation starting in the mucosa and might spread to all coats of the colon. His cases could be divided into the four groups: (1) those in which there was proctitis; (2) those in which the left half of the colon was involved; (3) those with involvement of the whole colon; (4) segmental colitis. The bowel symptoms in each group were what one would expect, and the general symptoms the results of toxaemia, loss of blood, disturbed digestion, and lack of sleep. The diagnosis must be confirmed by the proctoscope, the sigmoidoscope, and *x*-ray and bacteriological examinations. Proctoscopic examination confirmed the diagnosis in all but the segmental cases, in which radiography was essential. In the seriously ill patients bismuth enemata might be harmful and sigmoidoscopy dangerous.

The first and most important step in treatment was to confine the patient to bed, preferably on an open-air balcony. The diet should be the most nourishing that could be taken with the minimum of residue, and added vitamins. As regards operative treatment, ileostomy certainly rested the colon and the inflamed part could be removed by colectomy. Theoretically it was the ideal treatment; but mortality was high and the patient with a permanent ileostomy was not in a happy state. The operation should be reserved for complications, such as strictures and polyposis, and for cases that were obviously failing to answer to less drastic forms of treatment. In Mr. McEvedy's experience caecostomy was a definite help in curing an attack, but when the caecostomy was closed the disease returned with greater severity. This operation should be abandoned. The same applied to colostomy. Appendicostomy allowed the colon to be washed out in the most satisfactory way with the least discomfort to the patient, and permitted local application to the colon. This operation had not found the favour it deserved because surgeons generally had neglected its finer points, the after-treatment had not been thorough, the relapses had not been treated promptly, and too often the opening had been allowed to close.

Mr. McEvedy said that in his cases with proctitis he gave half a pint of saline with a teaspoonful of sulphanilamide per rectum each evening. This was generally retained. Relapses were treated promptly and the results had been most encouraging. In other cases an appendicostomy was performed as early as possible. Each evening the colon was washed out with saline followed by a pint of saline with a teaspoonful of sulphanilamide powder. Sulphanilamide and sulphaguanidine by the mouth had been disappointing. In only 5 out of 42 cases in the last five years in which appendicostomy was part of the treatment had the patients died.

MENTAL HEALTH IN WAR INDUSTRIES

At a meeting of the Section of Psychiatry of the Royal Society of Medicine on June 9, with Lieut.-Col. A. A. W. PETRIE in the chair, the effect of wartime industrial conditions on mental health was discussed.

Dr. W. BLOOD said that he was medical officer to an industrial concern engaged in food manufacture, employing several thousands of people on a working week of 48 hours, with overtime as required. In 1940 2.7% and in 1941 2.1% of all sick leave was due to psychological illness. Probably a certain number of cases masqueraded under "gastritis" or "rheumatism," so that the lost time was somewhat understated. The high figure for gastritis in 1940 (9.5%) might have some psychological significance on account of the conditions in that year (Dunkirk, air raids, etc.). A fair proportion of absenteeism otherwise unexplained was due to mental ill-health in its widest sense, or to fatigue. The increase in accident incidence he attributed to the entry of older and less experienced workers. It would be useful to have a medical psychologist attached to every accident clinic so that patients could be observed and put under treatment immediately any signs of depression after recovery from accident were noted. As it was, patients sometimes got steadily worse, and nobody troubled because it was nobody's business once the injury itself had been treated. Most foremen and managers said that workers were more "touchy" than before the war; this might be due to the fact that many were dissatisfied with their work but were unable to leave owing to the Essential Works Order. The doctor as well as the manager or foreman should be prepared to listen to troubles real or imaginary; if they were imaginary, mere patient listening often worked the cure, but sometimes the cause of the trouble, or of an aggravation of it, was found in the factory and could be dealt with by the management. Wages, hours of work, security, and conditions generally being satisfactory, he attached most importance to harmonious relations within the works, with full recognition of the worker as an individual, and to the development of social groups within departments. A well-run welfare department and sports clubs were useful preventive measures.

Women in Industry

Dr. JOAN HARWOOD said that she had been interested in a factory in an area not purely industrial, where many of the younger workers had left to be replaced by older people. The war effort had provided large numbers of bored persons with interests, and lonely persons with companionship, and had relieved the economic anxiety of some, while adding to that of others. Workers of the older generation had been given a heightened sense of their value, and absorption in work afforded relief of tension and depression following family separation. At the beginning of the war factories were badly blacked out and gloomy, so that it was necessary to work by artificial light, which was a frequent cause of depression; but with improvement in lighting and ventilation this was removed. Dingy canteens and poor cloakroom arrangements depressed the women, as did unsightly protective clothing. Long working hours, lack of sleep, and spells of night work were detrimental, especially to married women or women who had home responsibilities for dependants. Bad transport was another exasperating factor. Careful selection and placing of workers from the medical as well as the psychological point of view would cut down fatigue. Rhythmic exercises before a heavy meal were beneficial. The executive man or woman—especially the older woman—was a problem. The woman often received less toleration than she should at a time when she was feeling her age, but the average woman responded well to encouragement. The fear of losing her job was present to the older woman, though not in the same degree to the younger, especially if she was one of a group. Illness was often a synonym for homesickness. Higher pay for dangerous work had a good effect; people were more willing to fall in with safety precautions if there was a financial incentive.

Experience in the Last War

A paper by Dr. H. M. **Vernon** mentioned his experience during the last war, when this question was approached more from the medical than the psychological angle. Mr. Lloyd George at that time appointed a Health of Munition Workers Committee because of the sickness which was being experienced. At that time, of 1,300 women examined 35% showed some signs—and a further 7% pronounced signs—of fatigue or ill-health. A large proportion of the defects, including those put down to "indigestion" or to menstrual and other disorders, were of mental origin. It was found that on a 12-hour day accidents were three times greater than on a 10-hour day. Men appeared to be much less affected by long hours of work than women. The principles of industrial medicine established during the last war had been too much neglected. A considerable proportion of both male and female workers were engaged for excessively long hours—ten or more a day—and it was only too likely that these and other unsatisfactory wartime conditions were adversely affecting the physical and mental health.

The **President** said that there was a limit of hours—about 56 a week for women—above which the worker could not go satisfactorily. Many women were trying to do a double job, and it was marvellous how they did it. More emphasis should be placed on reasonable shopping facilities and an easement of transport difficulties.

Dr. **Millais Culpin** said that a medical staff which could handle difficulties would keep down the sickness rate in a factory. There was a wide difference in peacetime in sickness rates in different factories; it varied from 3 or 4 days per head per annum to 18 or 19 days. It was an advantage to interview the workers and encourage them to talk. Rest pauses were most necessary in concentrated work, and research was needed as to how long those pauses should be in work of different types. A good deal of the investigation carried out in the last war had been overlooked, particularly with regard to long hours of work. In many cases the 10-hour day produced a better output than the 12-hour. In questioning workers he had found a correlation between sickness rate and dissatisfaction with the job.

In some further discussion Dr. T. O. **Garland** suggested that it was not good to separate illnesses predominantly psychological from those predominantly physical; the problem should be viewed as a whole. He said that few doctors could be spared for industry, and it was an immediate task to instruct shop stewards, union officials, and the like in matters of simple health, psychology, and accident prevention. Dr. S. L. **Simpson** commented on the absence from the discussion of any reference to nutrition. There was some vitamin C deficiency; scurvy was only one expression of it, and there were substates of which fatigue and irritability might be manifestations. The discussion had concentrated on the mental health of the workers, but the mental health of managing directors and others occupying important posts must not be overlooked. This called for special consideration by all interested in industrial psychology because of the effect throughout the organization.

Dr. **Skottowe** suggested that an attempt should be made to separate mental illness of endogenous origin from upsets which were superficial and obviously connected with the environment. Major **Dicks** thought that forms of labour transfer as used in the Army might be employed by the Ministry of Labour so that workers could be placed in the job for which they were most fitted, and Major **Wilson** asked if there were some elementary intelligence tests which might be applied by welfare workers and would prevent the dull and backward from being misjudged and misdirected.

POSTURE IN INDUSTRY

At a meeting of the Association of Industrial Medical Officers, held at the London School of Hygiene and Tropical Medicine, Prof. H. A. **Harris**, Cambridge, spoke on posture in industry. There were, he said, four elements in the maintenance of posture: (1) proprioceptive impulses from muscles, tendons, and joints; (2) semicircular canal impulses; (3) evidence of the visual fields; (4) tactile sensations, especially from the soles of the feet. The sum total of these four gave the information to the brain which was necessary for the determination of posture. In fact, posture might be described as the "neuromuscular mechanism by which man keeps himself right side up with the world, so that the world would appear right side up to him." If the influence of any of the above factors was absent, then steadiness or maintenance of position would be upset. As an example, he referred to the importance of the feet being warm and of wearing footwear to which one was accustomed when in such a position that the tactile sense of the feet helped to maintain position.

There were certain critical movements, the integrity of which was important if the body was to function properly as a satisfactory machine: (1) Rotation of the head, which was controlled by muscles supplied by the cervical nerves and by the spinal accessory nerve. (2) Abduction of the eye-ball; here the muscles responsible were the lateral recti (the sixth cranial nerve). (3) Abduction of the vocal cords for phonation, activated by the laryngeal branch of the vagus. (4) Supination of the forearm; this was controlled from branches of the musculocutaneous nerve, the fibres being derived from the sixth and seventh cervical segments. (5) Abduction and adduction of the fingers, controlled by the deep branch of the ulnar (C_8 T_1). (6) Opposition of the thumb, activated by the median nerve, which contained fibres from the sixth, seventh, and eighth cervical segments. (7) Eversion of the foot. This movement, which was among the last acquired during the process of a child's development, depended on the integrity of the external popliteal nerve; the grave disability which followed Pott's fracture was the result of inability to perform this movement freely. (8) The action of the gluteal muscles was important in that these muscles controlled movement of the body forwards from the standing-still position, from sitting to walking, and in speeding up of pace, carrying, etc. They were enervated by the gluteal nerves, which contained fibres from the fourth and fifth lumbar and the first sacral segments. It was noticeable that when any of these critical movements were interfered with, one of three nerves was usually affected. The sixth cranial nerve, the ulnar nerve, and the superior gluteal nerve appeared to be most vulnerable to attack by injury or disease. The gluteal nerve, which consisted of fibres from the fourth lumbar segment, followed a very complicated course; this might be, in part, responsible for its vulnerability.

Prof. Harris then referred to the importance of remembering the ages at which certain epiphyses joined up, so that the strain of heavy lifting might be avoided at an early age where this would be dangerous. He cited the coracoid process, to which the biceps muscle was attached, and the ossification of the pelvis at puberty. The epiphysis of the coracoid process joined up at the age of 15; for this reason heavy lifting by young boys should be avoided. The centre of the os innominatum did not attain full bony maturity until the age of 18; before that age girls should not be called upon to stand for long periods. Many accidents were due to the fact that cramped posture did not allow muscles to respond rapidly when they were needed to do so. In conclusion, Prof. Harris said he was often asked whether factory work might not have a deleterious effect on women's health. Provided there was intelligent awareness of certain elementary medical and physiological facts, there was no reason why this should be so. A brief discussion followed.

Correspondence

Social Medicine

SIR,—I should like to thank both Sir Robert McCarrison and Prof. Charles McNeil (July 11, p. 51) for their endeavours to amend my definitions of social medicine. The term is so broad and comprehensive that it was perhaps unwise to attempt a definition at all, and yet I felt that the importance and interest of the subject required a clarification of its meaning. Sir Robert, suggesting the omission of the word "clinical" from my first definition, rightly asks—"For is it not largely because doctors have confined themselves to clinical (or bedside) medicine that the ultimate causes of disease have been neglected and the progress of medicine delayed?" But we could as justly ask in return—"Is it not because the study of aetiology has fallen so largely into the hands of the laboratory worker, who concerns himself with the intimate causes of disease, that the ultimate causes have been neglected?" Neither the clinician nor the laboratory worker has sufficiently studied his problems "in the field."

The good clinician concerns himself actively with all the human aspects of his problem—personal, genetic, and environmental—and has at least some of the opportunities and training of the "field worker." He has not hitherto been able to secure the opportunity of extending his activities to include the fuller study of environment, or taken it upon himself to recommend many changes in environmental conditions which he knows he could (given the opportunity) prove to be detrimental to human health. The training and office of the medical officer of health, on the other hand, although they may some day do so, do not at present secure for him the clinical opportunity to fit him for the new and larger tasks of social medicine as we begin to visualize them. It was for reasons of this kind that I included the word "clinical" (employing it in its widest sense) in order to emphasize the importance of this intimate human relationship, of the study of man *in* his environment, for without this no student of social medicine will ever fully justify his tasks.

While agreeing with Prof. McNeil's desire to lay stress on the preservation and advancement of health as opposed to the prevention and cure of disease, I do not think that "applied physiology" would be as apt a definition of all that social medicine intends as my abbreviation "applied aetiology." Physiology is concerned with the study of nature or function and so can help to establish standards of healthy function. Aetiology is concerned with the discovery of the causes of ill-health and so of the conditions necessary for good health. Social medicine is concerned with the practical applications of such discovery.—I am, etc.,

Guy's Hospital, London, S.E.1. JOHN A. RYLE.

SIR,—Prof. John A. Ryle's letter (June 27, p. 801) is balm to the worker in public health. May I be allowed to welcome it as the first sign I have yet seen from the hierarchy of the profession that their view of disease is, by contract of their calling, 'grossly and unscientifically limited by the walls of hospital and consulting room? One may even go further, and suggest that the "ultimate causes" are of equal status with the "intimate causes"—the specific factors, "bacillus, chemical poison, or vitamin deficiency"—to which, as Prof. Ryle says, the teaching and indeed the whole theory of medicine have been generally confined. The teaching of medicine needs be now radically reformed in the light of the generally accepted view of its object as "positive health and the prevention and cure of disease." Positive health requires the extension of physiology beyond the normal functioning of the body in normal surroundings to the limits of capacity and endurance of each organ and function; to the defence of the body against physical or biological attack; and to the application of physiology in the mass to the living conditions of the community. This surely is the only proper scientific introduction of the student to the medical profession in the new and wider light of its objects; it should be the basis of teaching for the specialty of public health. Is this not then the "Social Medicine" advocated so well by Prof. Ryle?—I am, etc.,

Hatfield, Herts. FRANCIS FREMANTLE.

Practical Results of Diphtheria Immunization

SIR,—What immunization can accomplish in combating diphtheria is shown by the remarkable drop in its incidence in Brisbane. The local authority of Brisbane has an area of 375 square miles and a population of 341,000. In January, 1938, I decided to make every effort to speed up the council's free immunization service. I used every available means to impress upon parents the importance of having their children—*especially their children of pre-school age*—immunized. The response exceeded my most sanguine expectations.

In the 4 years and 3 months period—namely, from January, 1938, to April 30, 1942—I have fully immunized 27,217 children. This rate of immunization in Brisbane, which is averaging approximately 6,400 per annum, is, in the period under review, considerably in excess of the birth rate. To this must be added an unknown but considerable number of children immunized by private practitioners in Brisbane, and I am pleased to be able to state that as I write the response of children is still being maintained. Records disclose that at least 75% of this total are children of pre-school age. By educative methods the stage has now been reached in Brisbane when the vast majority of parents realize that they owe this simple duty to their children.

The maximum incidence of the disease occurs during the second, third, and fourth years of life, and as large numbers of immunized children of this age group are appearing every day in increasing numbers in Brisbane the incidence of the disease now shows the anticipated spectacular fall. The following are the figures for this period:

	1938	1939	1940	1941	1942 (3 months)
Population ..	325,890	326,000	333,560	335,520	341,000
Diphtheria cases	459	505	231	202	22

Brisbane now has at least 80% of its susceptible child population immunized; the occurrence of only 22 cases for the 3 months of 1942 is a phenomenally low incidence in a population of 341,000 people, and the objective of a diphtheria-free Brisbane for which I am striving is, on these figures, soon to be attained.—I am, etc.,

RALPH WEAVER,
Medical Officer of Health.

Brisbane.

District Nursing Service

SIR,—Evidence accumulates that much too little use is made by doctors with panel practices of the facilities afforded by the district nursing service. In far too many cases the doctor is insufficiently aware of the benefits which that service can render to his patients, and some doctors seem almost wholly unaware even of the existence of the service. The insistence now placed by the Ministries of Health and Labour on the advisability of close liaison between the factory medical officer, nurse, or welfare officer with the local district nurse and with the panel doctor makes it all the more important that the panel doctor should make more use of the district nursing service, though the benefits to be derived from it are applicable not only to active workers but to every class of panel patient. A recent illustration to which my attention has been drawn is that of an employee at a large aeronautical factory who was absent from work for a fortnight owing to cellulitis. Her panel doctor advised her to rest, but also to attend daily at his surgery, to which she had to walk some distance. Although this patient was actually a contributor to the district nursing service, the doctor never thought about putting her in touch with the district nurse, which she had not the initiative to do for herself.

I cannot too strongly urge, particularly in these times when doctors and hospitals are much overworked, that panel doctors, as well as the welfare organizations of factories, should bear strongly in mind the relief which can so often be given, both to their patients' ailments and to their own time, by the use of the district nursing service which is almost universally available.—I am, etc.,

HORDER,
Chairman of Council, Greater London Provident Scheme for District Nursing.

Mass Examination of Sputum

SIR,—In view of the proposed employment of wholesale *x*-ray screen photography for the detection of so-called symptomless pulmonary tuberculosis would it not be as well first of all to concentrate more fully upon detecting those numerous cases which do show one of the most obvious and characteristic symptoms—i.e., the presence of sputum? We know only too well how many patients presenting themselves to busy practitioners, complaining chiefly of cough and sputum, are regarded as "colds," catarrhs, winter coughs, influenza, bronchitis, asthma, etc., and in how few cases the sputum is examined as a routine measure. It is this routine "mass" examination of sputum which should be made possible, and almost compulsory, for every practitioner to obtain by the extension and amplification of laboratory facilities throughout the country, with provision for concentrated and specialized examination. Unlimited sputum-sample outfits should be supplied to all G.P.s, and a nation-wide campaign instituted on the importance of this routine procedure in every case where sputum is likely to exist.

It would naturally be understood that a finding of "Negative for tubercle" in such an examination might have no significance whatever, and the referring of suspected cases for further investigation should in no way be affected, even intensified. Thus no sense of false security would be engendered by obtaining negative results, and numerous cases of early and active infectious disease and chronic "carriers"—i.e., the true danger to the community—would be brought to light. If such a procedure were universally adopted, I am sure that every patient would very quickly come to expect that a sample of his sputum, whenever present, would always be required for examination as a matter of ordinary routine.—I am, etc.,

Leonard Hearn,
Senior Tuberculosis Officer
Nottingham.

Passive Movements for Joints in Paralysed Limbs

Sir,—There has been no time in our surgical history when there was more lively interest in the treatment of fractures and injuries in general. The physical treatment of these conditions is now well understood, and there is general and well-deserved condemnation of passive movements. But our good intentions may sometimes carry us too far, and passive movement has become such a bogy that we forget it may have its uses. After nerve injuries and other paralytic conditions such as poliomyelitis, active movements cannot always be performed for the very simple reason that there are no muscles to carry them out. In such a case serious stiffness may result and in joints that are anatomically normal.

We have been called upon to deal with many rather tragic cases in which the joint stiffness was so severe that the disability resulting from it far outweighed that from the nerve injury. Several of my colleagues working elsewhere, in discussing this problem, have said: "But does it really matter? You can always get rid of the stiffness if the joints are normal." In some cases, I agree, you can, and it takes many weeks of very hard work, so causing quite unnecessary delay in the repair of the nerve lesion. In a few cases, especially in the shoulder and hand, the stiffness is permanent and sometimes quite disabling.

Just what is the objection to moving a normal joint passively? I can see none, so far as the joint itself is concerned. It stretches the paralysed muscles, but is this harmful? There is not one shred of evidence to show it. Prolonged stretching may do harm; occasional gentle stretching within a normal range is almost certainly innocuous. The trouble is that we think of splints for nerve injuries as we do for fractures—in terms of immobilization. A paralysed limb should not be immobilized; it should be splinted so that the affected muscles are relaxed, and if movement can be allowed within the range of relaxation so much the better. This principle underlies the design of the splints for nerve injuries worked out at this hospital by W. B. Highet (*Lancet*, May 9, 1942, p. 555), but even these appliances cannot be used to the best advantage if passive movements are neglected. If a patient is not instructed in the daily movement of a paralysed limb it is better not to splint him at all, for the worst stiffness comes not from simple neglect, though that may be bad enough, but from uninterrupted splinting; it is particularly pernicious when a faulty appliance is used, such as the "fish-server" cock-up splint that disgraced the E.M.S. equipment at the beginning of the war.—I am, etc.,

Wingfield-Morris Orthopaedic Hospital, Oxford H. J. Seddon.

Sacro-iliac Strain and Subluxation

Sir,—I was interested in the letter by Mr. C. Jennings Marshall (Jan. 3, p. 22) dealing with sacro-iliac strain and subluxation. I agree that an appreciable number of sufferers from chronic backache are allowed to go on suffering owing to the fact that the real cause is unrecognized. It would be pleasant to think that chronic backache due to a sacro-iliac lesion will be as rare as the wrist-strap, once a familiar token of the unrecognized fractured navicular bone.

X-ray films will not show any evidence of the condition known to surgeons as sacro-iliac strain. Mr. Jennings Marshall describes a method by means of which it is claimed that subluxation can be recognized. This method is commonly used by surgeons, and it consists of drawing a line across the film joining the tips of the fifth lumbar vertebral transverse processes, and then drawing another line across the film through the pubic crest; it is claimed that "rotation" can thus be shown. Others draw the first line across the film as above, and a second line joining the iliac crests; if these lines are not parallel, it is claimed that there is sacro-iliac subluxation.

It appears to me that a good deal more faith is placed in the immutability of the bony points of the pelvis than is warranted. The lumbar transverse processes are notoriously irregular. I drew these lines on a number of films of normal pelves, joining a number of different points, and I found that they varied considerably. The pelvic girdle is not necessarily a symmetrical structure. The only absolutely valuable sign of sacro-iliac subluxation which is recognizable at once is that the ilium on one side is superimposed over the sacrum to a greater extent than on the other. I do not think that subluxation should be diagnosed in the absence of this sign. Manipulation can give excellent results, and I have seen dramatic cures effected, but I do feel that these lines are inaccurate, and may make the diagnosis something of a fetish.

The sacro-iliac joint is often badly radiographed. The patient should be placed on the couch absolutely straight, which is not always easy; for a difficult case I can recommend that a fluid level be placed across the two anterior superior iliac spines. The whole pelvis should be included on the film. It is best to tilt the tube about 20 degrees towards the head, centring just above the symphysis pubis. Postero-anterior and oblique views are sometimes useful, but in every doubtful case stereoscopic films should be taken.—I am, etc.,

John A. Ross,
Major, R.A.M.C.

Complacency in Anaesthetics?

Sir,—Interesting as have been the letters under the heading "Complacency in Anaesthetics?" it seems to me that some essential points have not been made, and as one who has been an active specialist from a "rag-and-bottle" studentship until now I may claim some authority to speak.

The real complacency is not "modern"; it dates back to "rag-and-bottle" days and consists in essence in the fatuous assumption that anyone who has taken a qualifying diploma is thereby fitted to give anaesthetics. No one in his senses would allow the latest-joined house-physician, or assistant in general practice, or other junior who happened to be "odd man" at the moment, to remove an appendix without proper supervision; yet such are habitually allowed (or perhaps compelled) to give anaesthetics, although the life-and-death responsibility lies more heavily in the great majority of cases on the anaesthetist than on the surgeon. This state of affairs was deplorable enough when there were at most two or three anaesthetic drugs in general use, but it is exaggerated to the point of a public menace now on account of the multiplicity and complexity of anaesthetic agents and procedures.

The minimal requirements in anaesthetics for qualifying diplomas are so ridiculously inadequate for practical work that no one who has not done a postgraduate course of the most exhaustive kind should be permitted to administer without expert supervision. (Even the D.A. is no real protection against the theorist devoid of the necessary judgment.) Yet it is almost impossible to get medical men to attend such courses. Although the expenditure of time and money would be very slight, the horrid figure of complacency or *amour propre* stands in the way, and the usual attitude is that every qualified medical man "knows all the answers" and that anaesthetics need no special study. That there are other and less creditable motives than mere complacency for not employing specialists we all know, and I refrain from labouring the point.

If there has been any deterioration in anaesthetic mortality figures, which has not been shown to date, there are many factors which would easily account for it, such as: (1) The constant introduction of new anaesthetic agents used only too often by persons without the necessary anaesthetic, therapeutic, or physiological knowledge, and the unavoidable element of experimentalism thereby involved. (2) The fact that so many of these agents are intravenous, making the amount of judgment required much greater. Drugs once put into the bloodstream cannot quickly be got out, and damage is irreparable before it is obvious. (3) The enormous amount of operating now done relative to the supply of anaesthetic specialists. (4) Surgeons have come to rely on the safety of the expert anaesthetists and credit all administrators with the same skill. They are, therefore, getting slower and slower in surgical procedure. In the "old days" time was recognized as a serious consideration (who has not tired at the constantly repeated "Is he all right, doctor?" from over-anxious surgeons?). Whereas now, new and more tedious, if neater, methods of suture, elaborate skin-towelling, multiple operations under the same anaesthetic, application of plaster splints, *x*-ray control, and the infinitely greater scope of surgical intervention have put considerations of time far into the background, and placed a far greater tax on the resources of patient and anaesthetist.

Although I am certain that publication of more figures will dispel any tendency to alarm, the one way to improvement and non-complacency is surely to employ only specially experienced anaesthetists, and to increase the supply of them until no one need undergo any operation, in any but uncivilized parts, without such assistance. In so far as apparatus is more complicated and drugs more numerous, it is merely retrograde to deny to patients the benefits obtained from these advances, both during and after the operation, and to return to the crudities of "open" administration, merely because the latter is perhaps easier to teach to students and (save the mark!) nurse "anaesthetists." We do not limit surgery to the abilities of the latest-joined house-surgeon; let us insist on applying the same standards to anaesthetics as to surgery.—I am, etc.,

Stanmore. REGINALD KARN.

Urethral Instrumentation

SIR,—How unhappy to-day is the lot of the medical practitioner! Slowly but surely he is being stripped of his competence to perform all those simple procedures he learned in his student days and believed, and was taught to believe, that he would employ for the benefit of his patients and for the sake of his living in postgraduate life.

Ante-natal treatment, midwifery, child welfare, anaesthetics, immunizations, and minor surgery are all being filched from him by the public health experts (canvassing by advertisement) and by ever-increasing numbers of specialists. In fact, I have heard it said that nowadays all a practitioner needs to run a practice in a densely populated area is a pen, paper, stethoscope, thermometer, and catheter. And now my old friend Mr. Gordon Bohn writes to say that the general practitioner must discard the catheter and replace this valuable instrument of general practice by the telephone. He writes to challenge Mr. Clifford Morson's statement that a "general practitioner will benefit his patient by passing a catheter" in a case of acute retention, and even suggests that senior students be taught when not to pass a catheter, with acute retention due to an enlarged prostate heading the list of their restrictions. He honours us by assuming that we may avoid making a false passage and that our aseptic technique is beyond reproach, but he fears that in the excitement of the moment we may let off all the urine and kill the patient by anuria and bleeding from the kidneys. In spite of granting us asepsis and faultless technique he dubs our efforts as "interference by the practitioner," which of all his implications I find the hardest to receive.

Mr. Bohn believes that we should send all our cases of acute retention immediately to hospital or nursing home before the retention is relieved. In ideal surroundings Mr. Bohn is making a scientifically sound statement, and given a willing patient in little pain, a fast ambulance, a smooth road, and a good urologist in waiting, I can imagine no circumstances more propitious for avoiding the horrible catastrophes he mentions.

Personally, I am never more conscious of my halo than when I have turned out at night to catheterize some poor old man who has been in agony all day trying to pass his water, and, due to my interference with a rubber catheter, experiences that glorious relief a taste of which may be experienced by the ordinary man who has to hold his water a couple of hours longer than he likes. Perhaps unduly biased by the patient's gratitude, it is difficult to believe that in catheterizing him one has sinned against the laws of urology, instead of performing an act of mercy if not of competence. I have examined my surgical textbooks and the *B.M.J.* back to 1938 for another authoritative opinion, as I consider the matter of great importance. The last article in the latter was by Mr. R. Ogier Ward (Jan. 21, 1939, p. 121), and although only three years past, it seems to uphold my conception of procedure. As I understand it, one's duty is to take a history, examine the patient thoroughly, order a hot bath, give an injection of morphine, and if this fails proceed to catheterization. A soft rubber catheter of average size passed with full aseptic technique is often successful, and, as Mr. Ward points out, is a diagnostic as well as a therapeutic measure. If this fails, a soft silk-web coudé catheter, correctly sterilized, may be introduced. If the bladder is not distended above a third of the way to the umbilicus it is presumably safe to run off most of its contents forthwith. If, on the other hand, there is a history of chronic retention, greater distension, and any uraemic signs, gradual decompression can be carried out with a drip-saline bulb attached to the catheter, and hospital treatment discussed with the patient when he is more comfortable. In any case of difficult catheterization the patient should be sent to hospital before trauma results.

As acute retention occurs in those generally well advanced in years, I think it is necessary not to be too precipitate in pushing the patient into hospital. Hospitals and operations are not always as acceptable to the old as to the young, and personally I never use the urgency of the patient's disease as a lever to get him into hospital unless forced to do so. Often the acute retention patient is debilitated from other causes, and there can be very little object in forcing into hospital an old person whose days are already numbered, if by so doing he may live a little longer, but in discomfort from investigation and procedure for which he has but little stomach. Mr. Bohn's procedure is to be recommended in his own district, where all the facilities abound, but in a district like this primary catheterization by the practitioner at home should be justifiable for diagnosis and treatment. It has also the virtue of retaining the patient's regard for the practitioner, which is apt to dwindle if relief is withheld on technical grounds.

In conclusion, may I ask Mr. Bohn to elaborate his advice and describe what happens to the patient when admitted to hospital in his district. I should like to add that in spite of the increased sale of penile clips following perurethral resection, I consider that method to be the one of choice for dealing with enlarged prostate, and I should be loath to disqualify my patient for this operation by performing a single careful catheterization. I cannot, however, believe that I should.—I am, etc.,

St. Ives, Cornwall E. C. ATKINSON.

SIR,—With reference to Mr. Clifford Morson's letter (June 20, p. 771) I, and I am sure many of the older general practitioners, would owe a debt to Mr. Morson if he could spare the time to let us know the present-day teaching of how to pass a silver-plated old-style catheter on the living adult subject whose urethra is not diseased or deformed. We were taught to do this in the long past on the dead subject in the dissecting room, but, though this was simple, in practice on the living patient it was far from simple. Matters have of course moved on since our student days. The subject is a most important one. —I am, etc.,

Clogher, Co. Tyrone. HENRY SMITH, M.D.

Post-vaccinial Encephalitis

SIR,—Flight Lieut. G. D. S. Briggs's description (June 27, p. 791) of three cases of post-vaccinial encephalitis is of special interest to medical men in Scotland, where at the present there is a marked increase in primary vaccinations among the higher age groups. Dr. Briggs's cases appear to have been of the hyperkinetic type of encephalitis, and I herewith give a short report on a case in which the main picture was that of somnolence, altered sleep rhythm, and spastic paralysis.

The patient, a member of the W.A.A.F. aged 20, was admitted to hospital suspected of suffering from cerebrospinal meningitis. Vaccination had been carried out for the first time 10 days before, and on the day before admission she complained of headache, dry throat, pains in the limbs and back. She had also fainted. On admission a well-marked pustule was noted on the left arm with a fairly severe reaction spreading almost from shoulder to elbow. The patient was drowsy, but would answer questions on being roused. Photophobia, slight general rigidity, positive Kernig's sign, and exaggerated knee-jerks were all present. Babinski's reflex was indefinite, pupils were equal but reacted normally, but there was a marked spastic paralysis of the right arm. Lumbar puncture revealed a normal fluid not under pressure.

During the next five days the patient's condition altered little. On the sixth day the temperaure, which had remained between 100° and 101° F., became normal, but the patient remained drowsy during the daytime and suffered from sleeplessness during the night. Spasticity of the right arm was still present. On the thirteenth day of illness she was allowed up, but on the following day she complained of pain in the left lumbar region between the lower costal margin and the iliac crest; slight redness of the area being here noted, she was returned to bed. Eventually there developed in this region a patch of herpes about three inches in circumference. On the twenty-eighth day she was again allowed up, still slightly drowsy during the day and not sleeping well at night. Her general condition was poor. She was discharged on the forty-second day of illness greatly improved but still suffering from insomnia, which was clearing up.

The case was of interest, apart from the altered sleep rhythm, on account of the localized spastic paralysis of the right arm, a similar type of paralysis being noted about the same time in a child of 4 years who was suffering from early cerebrospinal meningitis, but in the latter case it progressed to involve the leg and the face on the same side.

It may be that, on account of the youth of most of the subjects of primary vaccination, the true incidence of mild post-vaccinial encephalitis is underestimated, a drowsy child during the daytime being accepted by the parent as a normal state of affairs, and a fretful child at night as being the result of the vaccination trauma.—I am, etc.,

J. Landess Horne,
Medical Superintendent.

County Infectious Diseases Hospital,
Strathpeffer

Serving Officers and Medical Planning

Sir,—There is one group—namely, medical men in the Services—which watches the discussions regarding post-war medical planning with anxious interest. The anxiety is due to the fact that many of us, with family responsibilities and faced with the prospect of making a new start after demobilization, feel that we are at a disadvantage. Although most vitally concerned, the very fact that we are under Service discipline makes us the most inarticulate section of the profession.

As a profession medical men claim to show disinterestedness in matters concerning the public weal. Nevertheless, although sincere, the fact remains that the judgment of most of us is liable to be affected by circumstances involving the fundamentals of our economic life. This is made clear when, as I have found during conversations, most Army medical men seem to favour some sort of national medical service, while those in well-established private practice are mostly "doubtful," to say the least. The object of this letter is to make a plea that the disadvantageous position of Service men should not be overlooked by those who decide the issues. The very fact of having been asked to make sacrifices should give them some claim for consideration.—I am, etc.,

"M.O."

The Planning Commission's Report

Sir,—The draft interim report resembles in many respects a pamphlet on the question of the minimum requirements for children.[1] We are now presented with the minimum requirements of the medical profession. It is hardly likely that it will meet with quite as favourable a reception as did the admirable report on the children.

No matter how excellent the plan may become in its final draft there can be little doubt that it will have to be hawked round the various political parties for support. It will ultimately be put into operation by the Government of the day, which may or may not be in sympathy with the views of the Commission. In this process the plan will be altered to suit this or that political expedient.

Would it not be better, as a preliminary step, if the Commission determined the patients' minimum requirements? They could find out, say, the 50 most common ailments met with in general practice as shown by a research of the National Health Insurance records. It could then lay down the minimum investigation and treatment required. It is doubtful whether the beds, medical, nursing, and technical staff, or the equipment are available, even in peacetime. Consideration of the financial aspect would but add to the general deficiency. Let the Commission consider these minimum requirements and tell the patients—i.e., the electorate—what is wanted. It will then be incumbent on the patients to demand these requirements if they wish them.

The profession would do well to by-pass the direct political approach, but to be ready with the prepared plan at the appropriate time should the pressure exercised by the patients prove sufficient.—I am, etc.,

Finsbury Health Centre, E C 1. A. B. Stewart.

Sir,—To a country practitioner the draft report is a disappointing, patchy, and urban production, which illustrates McDougall's point that the effort of a band of men is generally unworthy of any one of them individually. They have left out two-thirds of England, for para. 70 leaves us very much as we are now, and few even of the market towns have six doctors, the suggested minimum for a health centre; and of the difficulties of transport, which must carry the colds, chilblains, and colics—nine-tenths of a doctor's surgery—not a word. Truly a metropolitan myopia.

From the very start, from reading the objects of medical service and the first of the questions, so reminiscent of the League of Nations Union's "Do you prefer peace?" or the temperance reformers' "Do you deprecate drunkenness?"—pious blurbs embalmed in words, shop-window stuff—I became suspicious. Since when has it not been our aim to do our best for our patients? "Positive health" made me squirm. To my mind this nebulous phrase suggests leading a hygienic camp life with good food and keeping as far away from doctors as possible. Do these 73 elderly city fathers know anything about it? Did they deliberate in shorts and no collars in the open air, do they exercise every muscle every day, do they obey the seven rules of health, grasp the gifts of sun and air, defaecate at a squat? Have they taught the students these things or have they left it to the *Daily Mail* and the Boy Scouts? In fact, wasn't "positive health" coming from them rather nonsense?

The question of freedom of choice with us is academic. Two things compel a man to go to a certain doctor—geography and custom. He who lives at Little Snoring or Snoring Green will go to the Great Snoring doctor because he would have to go 7 miles to another, and even he at Snoring Virginibus, 6 miles away and so much nearer the Lower Sighing doctor, will gladly make the distance because his father did.

Of course there are many suggestions that will meet with almost universal approval, and although, personally, I should prefer to build on to or alter the house where Sydenham lived, where Hunter worked, which Osler has not long left, I can quite understand that young men want something more drastic done. For don't let the commissioners imagine for one moment that they have exhausted half the possibilities. A whole-hog scheme, for instance, with a great central health and hygiene house, with forty million dossiers recording the physical history, illnesses, work, holidays of everyone in these islands (a genetic map could be added probably towards the end of the century) from the time when he or she was a mere movement in foetal life or before, till they come to the necropsy table, a scheme which will try to prolong in happiness and usefulness the interval between these events, a scheme of which the patient is really the centre and the doctor merely serves to that end, has at least the merit of being logical.

---

[1] Issued by the Children's Minimum Council, 72, Horseferry Road, S W.1.

At any rate there is no hurry. The Ministry of Health has told us that the health of the country has never been better, and, personally, I have been looking round in vain for the patients who would have benefited had any of these schemes been in operation years ago. Significantly and monitorially the one exception is tuberculosis, a disease that has been a Government responsibility for years, employing an army that has always seemed to me to have a positively "Whitehallian" lack of punch. How rarely one hears of a keen, cavity-squashing, sputum-blitzing T.O.! My experience is of quite charming, unworried roundsmen. Who ever heard of a T.O. being appointed because of his aggressiveness against T.B.s? Probably if he were he would soon run up against the county M.O.H., who is also chief T.O., although he may know little about it. Anyway it is a relief to see the proposal (para. 14) that the appointments should no longer be made by the butcher and baker.

Truly this report is meat for discussion, but where are the vultures? I resent the note of hurry, not so much in the report itself as in the last paragraph of the leading article that accompanied it. Shall Libyan sands re-echo to debate and ward-rooms thunder? For in like places are the best of us. Never was time nor temper nor space for script less suited for discussion. Let us beware of the fate of the extinct Iwash Indians, of whom it is recorded that when in time of war the young men were away, the old men violated their wives, so that when the warriors returned they slew (1) the old men, (2) the unfaithful wives, (3) the young bastards.—I am, etc.,

C. G. LEAROYD.

Diphtheria in an Infant

SIR,—I should like to report that I have recently had a case of diphtheria in a baby 12 days old, born in the maternity ward of Honiton Infirmary. It was healthy at birth, and on the twelfth day was found to be snuffling; the following day the throat looked suspicious and swabs were taken. The Devon County bacteriologist reported as follows: "Cultures made from swabs of throat and nose were found to be positive for diphtheria. A virulence test on guinea-pigs was made from both cultures, and in both instances the test guinea-pig died within 48 hours of inoculation, and showed their typical post-mortem signs of death from diphtheria."

The baby's mother had no evidence of any infection of nose, throat, or vagina either before or after confinement. Swabs have been taken from everyone who came in contact with the child, with negative results.—I am, etc.,

Sidmouth. C. M. B. CASE.

The Rheumatic Lung

SIR,—Dr. James Burnet stated (June 27, p. 804) that he was probably the first to call attention to this condition. However, A. E. Garrod, in his *Treatise on Rheumatism and Rheumatoid Arthritis*, London, 1890, pages 106-9, gave a good account of the rheumatic lung, and the possibility of the "rheumatic poison" causing pneumonia was considered. And Garrod was probably not the first.—I am, etc.,

London, S.E 10 ELI DAVIS, M.D., M.R.C.P.

China's Medical Needs: An Appeal

SIR,—The China Medical Aid Committee appeals again to your readers to assist the National Red Cross Society of China. In the past these appeals have been generously answered, and now that China is our ally in name as well as in deed we put forward our appeal with even more confidence.

Three years ago 19 medical men, who had been rescued from concentration camps in the South of France at the end of the Spanish War, were sent to help the Chinese Red Cross, who had asked urgently for trained medical men as well as supplies. This committee, in co-operation with a Norwegian committee, financed and equipped these men and provided their maintenance so that the slender resources of the Chinese Red Cross should not be drawn upon. The help of the Norwegian committee ceased in 1940, and we are the only body to which these doctors can look for support.

The doctors are working on various sectors of China's immense war front, and two have been in the thick of the Changsha battles. All of them are doing invaluable medical and surgical work, and, in addition, organize first-aid training and teach hygiene to soldiers and civilians. They lead the simplest and hardest of lives. The following report, written by a young English doctor, is typical of work in South and Central China.

> "Our unit had charge of 100 beds in the hospital, which was otherwise run by the military. But the latter had neither the equipment nor the personnel to cope with the more serious cases, and these all came to us. Most of the cases we had were very severe compound fractures and chest wounds that had survived the first week or so. The abdominal and brain cases we saw little of; they had died before they could be brought to us. But the fractures were bad enough. They had come in carried on make-shift stretchers. Exhausted with pain, their wounds covered with pus-soaked and dirt-stained dressings, and with appalling deformities through lack of adequate splinting, they presented a sorry picture indeed."

The Chinese Red Cross has a task to carry out so enormous that the aid we give seems ridiculously small, but it is an earnest of our appreciation of the heroic resistance maintained by China, and we appeal to you to continue that help for another year. All donations should be sent to the treasurer, Dr. E. R. C. Hambly, Treharrock, Long Grove, Seer Green, Bucks.—I am, etc.,

MILLAIS CULPIN,
Chairman, China Medical Aid Committee

Obituary

WILLIAM MARTIN, M.B., Ch.B.

Dr. William Martin, who died suddenly on July 7, was appointed medical superintendent of Stobhill Hospital, Glasgow, in 1927, from Birmingham, where he had been medical superintendent of Selly Oak Hospital for about seven years. He was a graduate in medicine of Glasgow University, qualifying in 1914. He joined the Army in 1915 during the last war and served in France with the rank of major. On his return to this country in 1917 he was appointed to Dudley Road Military Hospital, Birmingham. Dr. Martin was unmarried, and is survived by two sisters.

Sir Alexander Macgregor writes: The death of Dr. William Martin closes the career of a distinguished and successful hospital administrator. He not only gave outstanding service to his own large hospital at Stobhill but also to the other general hospitals of the Corporation. After the passing of the Local Government (Scotland) Act, 1929, the Corporation took advantage of his experience by appointing him as deputy medical officer (general hospitals) in the Public Health Department. He came to this office with a high reputation for hospital administration. Under his regime great improvements were effected in Stobhill Hospital, such as, among others, the erection of a large *x*-ray and electrical department, an enlarged maternity unit, a receiving department, and a biochemical laboratory. Plans had been prepared for a new block for sick children and a new nurses' home. He took a prominent share in developing teaching facilities in the hospital, and the following extract from a letter to me from Sir Hector Hetherington, the Principal of Glasgow University may be quoted: "All of us here found in Dr. Martin a most able and friendly collaborator in developing the co-operation of the University and city in medical teaching and research, and we are much moved by his loss."

Dr. Martin was content with nothing but the best, and maintained a high standard of efficiency along with a clear and practical conception of modern hospital practice and development. On the personal side he was a most agreeable and attractive colleague; he was never ruffled by difficulties, and his happy and cheerful disposition was one of his finest assets, attracting the warm friendship and regard of the medical and nursing staffs and of all who served in the hospital in whatever capacity.

We regret to announce the death of Dr. RONALD LESLIE FERGUSON, honorary physician for children at the Manchester Northern Hospital. He was born in 1882 and studied medicine in Manchester and Dublin, graduating M.B., Ch.B. at the Victoria University in 1905 and proceeding to the M.D. four years later with commendation for his original studies on the digestion of fats, upon which he had worked in close co-operation with Prof. Craven Moore. He had been a member of the B.M.A. since 1908. Two colleagues (P. M. and G. W.) write: Ronald L. Ferguson held many resident appointments at Crumpsall Hospital, Ancoats Hospital, and the Royal Infirmary, Manchester. He also found time to go to the Far East. Later he started in practice in Manchester and pursued a busy and helpful life for 30 years, broken only by three years' active service in Mesopotamia. We realize that few really knew him because of his modesty and shyness, but once these were penetrated, how easily one could appreciate the goodness of the man and the genuineness of his purpose in all things! He was a good sportsman, an excellent bowler, and a capable batsman, and well merited his place in the University team for many years. He was an ardent follower of cricket at Old Trafford. His great sense of responsibility towards his patients caused him to work recently although he knew he was unfit to do so. His passing leaves many happy memories—to patients and friends alike—of a man whose honesty endeared him to those of us who were privileged to know him well.

Dr. **GODFREY BATEMAN**, who died on June 8, was a past-chairman and a past-secretary of the North-East Ulster Division. Son of the late Godfrey Bateman, LL.D., senior inspector of schools, Dublin, he was educated at Galway and Portora Schools and studied medicine at Trinity College, Dublin, graduating M.B., B.Ch., B.A.O. in 1915, and M.D. three years later. He obtained the D.P.H. of the Irish Royal Colleges in 1919 after serving in the last war as captain R.A.M.C. On returning to civil life Dr. Bateman began practice in Coleraine, and in 1930 was appointed tuberculosis officer for County Derry, a position he held up to the time of his death at the age of 49, after a long period of indifferent health. During his service in Coleraine, Portstewart, and Portrush, Dr. Bateman won the regard of all sections of the community, and in particular concerned himself with the welfare of ex-Service men, for whom he did good work as chairman of the local branch of the British Legion.

Dr. **WALTER ROSS JORDAN**, who died at Edgbaston on June 13 at the age of 78, was a nephew of Thomas Furneaux Jordan, the famous Birmingham surgeon, and his father also was a doctor. He was educated at King Edward's School, Birmingham, of which he was a Governor from 1917 till his death, and Bailiff of the Governors on two occasions; he was also one of the founders of the Old Edwardians Association and for some time chairman of its committee. He studied medicine at Mason College and the Queen's Hospital, and graduated M.B.Lond. (with honours in medicine) in 1887, proceeding M.D. five years later. After serving as resident physician at Queen's Hospital he was appointed visiting physician at Dudley Road Infirmary and physician to the Children's Hospital, Birmingham; for many years he practised as a consultant in Cornwall Street. Dr. Jordan published a number of papers on paediatric subjects and was a past-president of the Birmingham Branch of the British Child-Study Society. He had been a member of the B.M.A. for 50 years, was vice-president of the Section of Diseases of Children in 1911, and president of the Birmingham Branch 1915-19, in which year he gave the Ingleby Lecture at the University.

News has reached this country from India of the death of Dr. **SURENDA KUMAR DATTA**, Principal of the Forman Christian College, Lahore. Born in 1878, he was educated at Lahore Medical College and at the University at Edinburgh, where he graduated M.B., Ch.B. in 1906. He returned to Lahore as lecturer on biology at the Forman College, and was a member of the senate of the Punjab University in 1908-14 and again in 1934-42. During the last war Dr. Datta served as welfare officer with the Indian troops in France and was twice mentioned in dispatches. For a considerable time he was National Secretary of Y.M.C.A.s in India, Burma, and Ceylon, and he served three terms as chairman of the All-India Conference of Indian Christians, whose community he represented for three years in the Central Legislative Assembly. He was a member of Lord Lytton's Committee on Indian Students in the United Kingdom, and a delegate to the Indian round-table conference in London.

The following well-known medical men have died abroad: Dr. **EDGARD FILGUEIRAS**, a prominent paediatrist of Rio de Janeiro; and Dr. **ALVARA LEMOS TORRES**, professor of clinical medicine in the medical school of Sao Paulo, and Fellow of the Rockefeller Foundation, aged 58.

Universities and Colleges

UNIVERSITY OF LIVERPOOL

The following candidates have been approved at the examinations indicated:

M.D.—A. B. Higginson, C. K. Sconce.

FINAL M.B., CH.B.—*Part III:* Anita M. Beck, S. Bradshaw, E. R. Carter, V. L. Cooper, H. V. Cross, Jean M. Frazer, G. W. Gibbs, Patricia F. M. B. Gould, T. C. Highton, M. Horwich, R. D. Hotston, H. P. Hughes, W. B. E. Jones, J. Littler, R. B. McConnell, Jane C. S. Maclachlan, L. Mandel, A. J. Marsden, R. H. Maudsley, P. D. Moss, J. C. V. Murphy, S. P. C. O'Reagain, G. J. Rees, Hilda M. Reeve, G. C. Roberts, C. D. Rosenwald, D. I. Rowlands, T. L. Schofield (distinction in surgery), Betty W. Steiner, R. V. Tracy-Forster, Amabel M. Turner, D. C. Watson, H. H. Watts, W. D. Wilson, Rosalind Zalin. *Passed in Separate Subjects:* J. J. Bligh and R. H. Martin (Medicine, Surgery); J. G. K. Dean, P. J. Devlin, Joan O. Grant, and F. A. H. Inman (Medicine, Obstetrics, and Gynaecology); F. E. D. Griffiths, C. Pownall, and G. A. Wetherell (Surgery, Obstetrics, and Gynaecology). *Part I.* Ethel J. Higgitt, Margaret Slater, Elspeth M. Whittaker.

UNIVERSITY OF MANCHESTER

The following candidates have been approved at the examinations indicated:

M.D.—*By thesis:* J. R. Wardley.

FINAL M.B., CH.B.—[5]Alice Akred, G. Ashe, A. N. Ashworth, Pauline Blockey, [3,4]H. Bolton, H. A. Boydell, [2]D. M. Brierley, [2]W. E. Broughton, P. Cliff, J. G. Coburn, D. G. Crawshaw, Betty J. Dakin, Sheila Egan, D. Eglin, [3]K. Heap, Dorothy Hey, Esther Jackson, W. H. Lonsdale, R. L. Lunt, J. K. McMyn, C. W. Marsden, R. W. T. Mason, Ethel J. Samuel, H. F. Smith, [1,3,4,5,6,7]S. W. Moss, J. G. Oddy, S. Portnoy, P. T. Quinlan, A. Ramsden, F. C. Reidy, P. H. Renton, A. F. Robinson, M. M. Rose, B. Samuels, R. H. Sewell, J. H. Shelswell, Sylvia M. Slee, K. H. Smith, H. Sosnowick, J. L. Taylor, R. Tepper, Lois E. N. Turner, P. Vulfsons, E. G. Wade, Margaret Wardle, Ruth J. Whitley, T. A. Yates.

[1] First-class honours. [2] Second-class honours. [3] Distinction in medicine. [4] Distinction in surgery. [5] Distinction in forensic medicine. [6] Distinction in hygiene. [7] Distinction in preventive medicine.

UNIVERSITY OF ABERDEEN

At a graduation ceremony on July 9 the following medical degrees and diplomas were conferred:

M.D.—A. H. Cruickshank (awarded highest honours for thesis (*in absentia*)), D. A. Hunter (awarded commendation for thesis).

M.B., CH.B.—A. L. Stalker (with first-class honours, passed final examination with distinction), J. Mowat (with second-class honours), A. Adam, Mary R. Alexander, R. M. Allan, E. Anderson, R. M. L. Anderson, H. I. C. Bowie, Inez M. Brebner, D. D. Brown, I. MacD. Brown, A. P. Buchan, I. J. Buchan, Mary S. Buchan, N. Budge, J. Cantlie, T. L. Carr, J. R. W. Catto, Isabel M. S. Chalmers, I. G. L. Craig, J. L. T. Dickie, Margaret S. Duguid, D. M. Dunbar, Lorna L. Duncan, Eileen M. Duthie, G. W. Forbes, Helen S. Fraser, Leslie W. Fraser, W. G. French, R. Gibb, Isobel R. Grattidge, J. Gray, A. M. Gwynn, Muriel O. Henderson, G. L. Herbert, Eilean A. Hunter, J. G. Hunter, T. O'N. F. Kelly, Margaret C. Kemp, W. Y. Laidlaw, Agnes K. Leslie, J. C. Lightbody, R. K. MacCuish, J. C. M. MacDonald, W. H. McGillivray, W. B. McGowan, Dorothy J. Mackay, J. M. McKay, A. A. Mackie, A. H. McLaren, Mary E. C. Maclean, Muriel M. McLean, A. Mair, V. D. R. Martin, Elza H. Meadows, D. G. Milne, J. G. Murray, Cecilia M. Park, G. M. Reid, Alma C. Ritchie, Mary B. Robb, A. F. Ross, G. I. MacD. Ross, K. A. Ross, I. L. Roy, L. S. Rusack, J. K. Russell, A. G. Scott, G. M. Sinclair, Emily S. Smith, E. B. Smith, J. A. E. Stewart, A. B. Strachan, Cecilia V. Urquhart, A. Walker, S. J. M. Walker, W. A. Walker, W. Watt, Dorothy M. A. White, G. A. Wilson, J. H. Wood.

D.P.H.—Mary Anderson, C. T. Baynes, Enid M. Clow, Vera D. Davidson.

UNIVERSITY OF GLASGOW

At a graduation ceremony on June 26 the following medical degrees were conferred:

M.D.—A. G. Fergusson (with commendation), A. R. Hunter, B. T. Mann (*in absentia*).

UNIVERSITY OF ST. ANDREWS

The following medical degrees were conferred on June 27:

M.D.—J. Brodie (with honours for thesis and Rutherford gold medal), W. A. Davidson (with commendation for thesis and a silver medal), W. M. Jamieson, C. B. Macdonald.

M.B., CH.B.—*D. R. K. Reid, †G. Smith, †A. J. M. Mathieson, †J. D. B. MacDougall, †J. R. Anderson, †J. W. Smith, †Elizabeth M. McCracken, †Kamala P. Roe, †Jadwiga Mickiewicz, †A. Inglis, †Elsa R. Cooper, †W. M. C. Brown, †D. K. Stevenson, W. G. Birrell, W. W. Black, Mary Cammock, C. N. D. Cruickshank, T. D. G. Fairbairn, Isobel M. L. Fernback, S. Fuller, J. Gemmell, Muriel E. Gibb, D. M. Graham-Service, D. D. Inch, H. E. Kelsick, J. Millar, Janet Mills, Dorothea B. Irving (or Montgomerie), J. A. Petrie, D. E. Robertson, W. D. G. Robson, R. K. W. Sharp, D. McQ. Sibbald, A. R. Smith, W. G. Tait, Edith A. C. Thomson, A. M. Watt, Elizabeth D. S. Wilson.

* With distinction. † With commendation.

UNIVERSITY OF LONDON

Sir Ernest Graham-Little, M.P., has been reappointed as a representative of the Senate upon the Court of London University for a further period of five years from October 1, 1942.

UNIVERSITY OF DUBLIN

SCHOOL OF PHYSIC, TRINITY COLLEGE

The following medical degrees were conferred on July 1:

M.D.—C. G. Ambrose, J. E. C. Cherry, W. A. Gillespie, M. A. Majekodunni, Isabella M. Murphy (*née* Dorman), W. F. Rogers.

M.B., B.Ch., B.A.O.—J. M. T. Adamson, J. E. Adamson, P. St. G. Anderson, Violet K. St. G. Breakey, R. B. Brenan, Franziska G. Brill, D. M. Brooks, Helen U. Croasdaile, J. F. Dignan, J. B. FitzSimons, J. P. Hearne, W. J. C. Hill, E. K. Holland, A. M. Jacobson, H. H. B. Lamb, Dorothy W. M. Last, Margaret E. McClelland, J. McNutt, W. B. Martin, J. J. Musgrave, E. S. Odbert, S. Potgieter, A. W. Pringle, R. C. Rylance, H. Scheyer, K. M. Shaw, L. Shribman, S. B. Stein, F. S. Stewart, W. J. W. Wolfe.

QUEEN'S UNIVERSITY, BELFAST

The following candidates have been approved at the examinations indicated:

M.D.—W. McK. Bonnar (with gold medal), W. Townsley (with high commendation), W. S. L. Gilchrist, S. A. C. Hunter, J. S. Matthews.

M.CH.—C. C. D. Martin.

M.B., B.CH., B.A.O.—*K. Aterman, *J. M. Beare, *K. Bew, *D. J. Crawford, *H. C. Dales, *W. S. Hanna, *T. J. Harrison, *R. M. Laird, *Elizabeth F. M'Keown, *H. Montgomery, *E. Morrison, *M. R. Neely, J. H. Adams, Annie W. S. Beck, H. G. Biggart, W. Blair, A. S. Boyd, E. Boyd, R. B. Boyd, J. M. Bradley, P. D. Bradley, J. F. Breach, M. J. Brosnan, J. M. Bunting, Margaret S. Burns, F. C. Calvert, Margaret G. Calwell, A. N. Campbell, A. A. G. Carson, W. Castles, Sarah I. Cochrane, G. H. Connor, P. U. Creighton, W. P. Crone, H. J. Cronhelm, B. J. Cullen, J. Dewar, R. J. Dinsmore, W. J. Driscoll, R. Dunlop, A. S. Effron, C. M. B. Field, Mary I. Fleming, P. A. H. McC. Foster, T. Freeman, Margaret F. Fry, L. Ganz, J. G. Gibson, R. Halliday, R. S. Hamilton, J. A. G. Hart, D. Hay, D. Henderson, Henrietta E. Hunter, R. A. Hyman, Angel M. Jones, D. McM. Kennedy, W. A. Kennedy, A. I. K. Kerr, H. Kerrigan, H. L. Kyle, H. Lantin, A. A. McG. McConnell, R. A. McIlwraith, Mary J. C. McIntosh, Kathleen G. McKee, W. C. McKerr, J. S. McMaster, J. McRobert, J. F. Mark, A. A. McC. Miller, B. P. L. Moore, C. Moore, S. P. Moore, Margaret F. Mulholland, R. S. Murray, Yvonne A. Murray, G. P. Murtagh, J. F. Nicholl, D. A. R. Orr, H. F. Reynolds, Mary E. Ross, S. A. Scott, D. G. Simpson, R. T. N. Simpson, A. Sloan, D. G. Sloan, W. A. W. Small, S. M. Smith, A. E. M. Stevenson, J. C. Stutt, H. A. H. Summers, B. E. Swain, A. E. P. Swinson, G. O. Thomas, J. D. Watson, E. L. White, R. J. Young.

D.P.H.—S. H. Carson, J. M. Fullerton, J. H. P. Giff, A. Harbinson, R. Hill, W. H. Hood, A. Hyland, D. P. Kearns, I. M. Librach, J. S. McCann, W. J. McLeod, T. A. Spence.

* Second-class honours.

ROYAL COLLEGE OF SURGEONS OF ENGLAND

At a meeting of Council, held on July 9, Sir Alfred Webb-Johnson was re-elected President and Surgeon Rear-Admiral G. Gordon-Taylor and Mr. L. R. Braithwaite were re-elected Vice-Presidents for the ensuing year. Prof. G. Grey Turner and Sir Hugh Lett were readmitted and Brigadier Hugh Cairns was admitted to the Council.

The following professors, lecturers, and demonstrators were elected for the ensuing year:

Hunterian Professors.—Mr. W. H. Bowen, one lecture on a Study of the Aetiology of Acute Appendicitis; Mr. H. T. Roper-Hall, one lecture on Premaxillary Cysts; Mr. L. H. Savin, one lecture on the Surgery of Non-magnetic Intraocular Foreign Bodies; Mr. J. C. Ross, one lecture on Injuries of the Urinary Bladder; Dr. Raymond Greene, one lecture on Frostbite and Kindred Conditions; Mr. S. M. Cohen, one lecture on Traumatic Arterial Spasm; Mr. J. E. A. O'Connell, one lecture on the Vascular Factor in the Cerebrospinal Fluid Circulation and its Relationship to Intracranial Pathological Processes; Mr. O. S. Tubbs, one lecture on the Effect of Ligation on Infection of the Patent Ductus Arteriosus; Dr. A. G. McD. Weddell, two lectures on Cutaneous Innervation; Mr. W. B. Highet, two lectures on Injuries to Peripheral Nerves.

Arris and Gale Lectures.—Prof. H. A. Harris, lectures on (1) the Anatomy of Posture in Industry, (2) the Clinical Anatomy of the Veins, and (3) the Relation of the Lymphatic System to the Arterial and Venous Systems.

Erasmus Wilson Demonstrators.—Mr. L. E. C. Norbury, one demonstration on the pathological contents of the Museum; Mr. R. Davies-Colley, one demonstration; Mr. C. E. Shattock, two demonstrations; Surgeon Rear-Admiral C. P. G. Wakeley, two demonstrations on Injuries of the Skull and Brain.

Arnott Demonstrator.—Prof. A. J. E. Cave, six demonstrations on the contents of the Museum.

It was decided to recognize the posts of senior house-surgeon and first assistant house-surgeon at Essex County Hospital, Colchester, for the six-months surgical practice required of candidates for the Final Fellowship examination. It was also decided to renew the recognition of the post of house-surgeon at Walsall General Hospital for the six-months surgical practice required of candidates for the Final Fellowship examination, for the duration of the war.

Sir Frank Colyer was reappointed Honorary Curator of the Odontological Collection. The thirteenth Macloghlin Scholarship was awarded to John Alfred Gorton Holt of Bristol Grammar School. Miss H. B. Collard was reappointed a Leverhulme Scholar for a further year. A vote of thanks was given to Mrs. Rees-Mogg for presenting to the College a selection of 150 books from the library of her first husband, Dr. Edward Douty, F.R.C.S.

A Diploma of Fellowship was granted to R. S. Lawrie, M.B., M.R.C.P.

A Diploma of Membership was granted to J. A. Judson.

Diplomas were granted, jointly with the Royal College of Physicians of London, as follows:

DIPLOMA IN PUBLIC HEALTH.—R. Bhaskar, P. R. T. Naidu, W. Dodd.

DIPLOMA IN PSYCHOLOGICAL MEDICINE.—J. F. Cooper, H. Fleming, G. Garmany, Margaret J. Garmany, J. H. Gould, S. Leviten, P. Morris, J. Slorach, P. C. C. Treisie.

DIPLOMA IN LARYNGOLOGY AND OTOLOGY.—J. A. Harpman, C. McK. Johnston, E. Kaplan, E. C. Richardson, E. Rosenbaum.

ROYAL COLLEGE OF PHYSICIANS OF IRELAND

At recent meetings of the President and Fellows the following have been admitted Fellows of the College: J. A. D. Deeny, M.D., A. Whelton, M.D., John Duffy, M.D.

The Services

CASUALTIES IN THE MEDICAL SERVICES

Acting Surg. Lieut.-Cmdr. (D.) **ROBERT DOUGLAS JOHNSTON**, R.N., who was reported missing in the *Journal* of Jan. 10, is now posted as missing, presumed killed, in H.M.S. *Prince of Wales* in an Admiralty Casualty List published on July 10. He was educated at Edinburgh, where he studied for the dental profession, taking the diploma of L.D.S. in 1931. He also took the diplomas L.R.C.P.&S.Ed. and L.R.F.P.S.Glasg. in 1932. He was a member of the B.M.A.

Temp. Surg.-Lieut. **WILLIAM ANTHONY CAVANAGH**, R.N.V.R., is posted as missing, presumed killed, in H.M.S. *Repulse* in an Admiralty Casualty List published on July 13. He was born on June 27, 1908, and was educated at Dublin, taking the L.R.C.P.&S.I. in 1934. He had practised at Greencastle, Co. Donegal, since qualification, with the exception of a brief period in London in 1938, until the outbreak of war, when he immediately entered the R.N.V.R. as prob. temp. surg. lieut.

Prisoners of War.—Major D. C. Bowie, R.A.M.C., Capt. K. P. Brown, R.A.M.C., Major E. J. Curran, R.A.M.C., War Subs. Capt. R. L. Lancaster, R.A.M.C., Capt. J. A. G. M. Lynch, R.A.M.C., Major H. G. G. Robertson, R.A.M.C., Capt. J. E. C. Robinson, R.A.M.C., Lieut.-Col. C. O. Shackleton, R.A.M.C., Col. J. T. Simson, Major J. E. Swyer, R.A.M.C.

Missing.—Major C. A. Calder, R.A.M.C., Capt. E. T. M. Smith, R.A.M.C.

DEATHS IN THE SERVICES

Surgeon Rear-Admiral **GILBERT FRANCIS SYMS**, R.N. (ret.), died on June 23. He was educated at Guy's Hospital and took the M.R.C.S., L.R.C.P. in 1908 and subsequently the F.R.C.S. in 1923. After serving as house-surgeon and clinical assistant and out-patient officer at Guy's he entered the Royal Navy, attained the ranks of surg. cmdr. in 1919, surg. capt. in 1931, and surg. rear-admiral in 1938, retiring early in 1942. He served during the war of 1914-18, receiving the medals. He was appointed Honorary Surgeon to the King last year. He had been professor of surgery at Haslar Hospital and in charge of the Royal Naval Hospital, Plymouth.

Col. **STEPHEN FRAZER CLARK**, late R.A.M.C., died at Mosman, New South Wales, in May, aged 77. He was born on July 17, 1864, and was educated at the University of Edinburgh, where he graduated M.B., C.M. in 1885. In 1904 he took the D.P.H. of the Irish Royal Colleges. Entering the Army as surgeon in 1887, he became colonel in 1915, and retired in 1919. He served in the China war of 1900 (medals) and in the war of 1914-18, in command of a general hospital in France, and was mentioned in dispatches in 1914. He also received the Serbian Order of St. Sava (Third Class) and the Croix de Guerre in 1918. He had been a member of the B.M.A. for 35 years.

Lieut.-Col. **JAMES GIBSON MCNAUGHT**, R.A.M.C. (ret.), died at Penzance on April 25, aged 76. He was born in Glasgow on November 13, 1865, and was educated at the University of Glasgow, where he graduated M.A. in 1887 and M.B., C.M. in 1890, proceeding M.D. four years later. He took the certificate (with medal) in tropical medicine at the University of Edinburgh in 1894, and the D.P.H. of the London Colleges in 1903. Entering the Army as surg. lieut. in 1892, he became lieut.-col. in 1914, and retired in 1920. He served in the South African War in 1901-2, taking part in operations in the Transvaal, in Cape Colony, and the Orange River Colony, and received the Queen's medal with five clasps; and in the war of 1914-18 was mentioned in dispatches in 1914, and commanded the 13th Casualty Clearing Station during the Gallipoli campaign. He was a member of the Mediterranean Fever Commission of 1906 and was a frequent contributor on pathological and bacteriological subjects to the medical press. He had been a member of the B.M.A. since 1895.

Medical Notes in Parliament

Death Rates for Infectious Diseases

Mr. BROWN, replying to Mr. Leach on June 30, said that the death rates per 1,000,000 under 15 in England and Wales from the following diseases were, for 1939 and 1940:

	1939	1940
Diphtheria	227	265
Scarlet fever	15	12
Measles	34	95
Whooping-cough	140	78
Tuberculosis	240	264

The rates for 1940 were provisional. No rates were yet available for age groups in 1941.

On June 30 Mr. BROWN told Mr. Leach that the death rates per 1,000,000 persons living in 1938, 1939, 1940, and 1941 from small-pox, measles, scarlet fever, diphtheria, whooping-cough, enteric fever, cancer, and diabetes were as follows.

	1938	1939	1940+	1941+
Small-pox	0	—	—	—
Measles	40	7	21	28
Scarlet fever	9	4	4	3
Diphtheria	71	51	60	64
Whooping-cough	27	29	16	57
Enteric fever, including typhoid and paratyphoid	4	3	3	4
Cancer	1,665	1,620	1,662	1,670
Diabetes	173	124	129	117

The rates for 1940 and 1941 were provisional. They were calculated on the total population of England and Wales for 1939.

Children Employed on the Land

Mr. EDE, on June 23, in reply to a question on the need for adequate medical examination of school children exempted from attendance in order to engage in agricultural work in any case where there was danger of overstrain on account of a child's physical condition, gave the following information. The Defence Regulation required that "if the local authority by notice in writing served on the parent or guardian of any child so requires, the child shall not be employed in agricultural work, or, as the case may be, in agricultural work of any nature, unless he is certified by a registered medical practitioner to be physically fit to be so employed, and it shall be the duty of a child's parent or guardian to take all reasonable steps to see that he is not employed in contravention of this paragraph." In the instructions issued by his Department to local education authorities, Mr. Ede continued, the following was included: "If the authority, on information received from the school medical officer, teachers, or otherwise, has reason to doubt whether a child is physically fit to undertake the work, exemption must not be granted unless a satisfactory medical certificate, which should wherever possible be given by the school medical officer, is received."

Viscountess ASTOR asked if it was possible to give these children one hour's rest in the middle of the day. It would, she said, make a great difference to their health. Mr. EDE said that where a child was employed for the whole day there was a requirement that a sufficient period of rest should be allowed, and there was a general desire that the children should not be employed for more than half a day unless it was absolutely necessary. Mr. RHYS DAVIES said that if these children, aged 14 years and upwards, went to work in a factory they were all medically examined. Why was there this difference? Mr. EDE replied that there were not sufficient doctors available to examine all the children on the spot without such delay as would frustrate the object of obtaining the help of children on the land.

Colonial Services

Presenting the Colonial estimates on June 24, Mr. HAROLD MACMILLAN said few of the Colonies had or were likely to have for a long time so large a reservoir of qualified local candidates that the population could itself supply all the administrative, scientific, professional, and technical experts needed. A mobile force of experts in administration, medicine, agriculture, etc., was needed who would be at the disposal of the Secretary of State to be posted wherever in the Colonial Empire they were most required. Mobility was still hampered by variations in local regulations, in salary scales, and so on. Unification of the Colonial Service had been going on since 1930. Much progress had been made, but to get a fully unified and mobile service needed not only direction from the centre but financial provision to equalize conditions of employment in the poorer and the richer Colonies. The Colonial Office had Lord Hailey's gifts at its service. With the help of eminent scientists he would advise on the organization of research work over the whole field, and would have half a million pounds a year to do it with.

Dr. MORGAN said that in Jamaica conditions of treatment of venereal disease were unsatisfactory. Mr. SORENSEN said a more drastic development of Colonial Medical Services should be planned. It was appalling that not one coloured woman nurse trained in this country had secured a position as matron or sister in any of the medical establishments in West Africa.

Eyesight of Factory Workers.—Mr. MALCOLM MCCORQUODALE told Sir Francis Fremantle on June 10 that about 12,450 accidents causing eye injury were notified under the Factory Acts in 1941. There were no special arrangements of a comprehensive kind for the services of ophthalmic surgeons to be available for factory workers as such, but in a few cases factory managements had made arrangements to assist their workers in obtaining advice from such surgeons or from sight-testing opticians.

British Sick in Iraq and Persia.—On June 16 Sir THOMAS MOORE asked the Secretary of State for War what was being done with the British sick in Iran and Iraq and whether convalescents were being transferred to less trying climates. Sir JAMES GRIGG said that British general hospitals and combined British and Indian general hospitals had been established for British sick and wounded in Iraq and Persia. In addition hospital accommodation was available in the hills in India for patients recommended for a change of climate.

Lead Poisoning.—Cases of lead poisoning notified under the Factory Acts were—1,258 in 1899, 207 in 1919, and 109 in 1939.

Dental Man-power.—Mr. BROWN informed Professor Hill on July 2 that in carrying out their tasks of finding dentists for the Services the Central Dental War Committee took every care to ensure that a sufficient number of dentists were left in civil life to cope with civilian demands for dental treatment, including those arising under National Health Insurance and the School Dental Service.

Pneumonia.—During the ten years 1932 to 1941 inclusive the average number of cases of acute primary and acute influenzal pneumonia notified annually was 50,912, with a maximum figure of 65,009 cases in 1933 and a minimum of 42,312 in 1939. Mr. Brown said that chemotherapy in the treatment of pneumonia was introduced about six years ago and had come into general use since 1938.

Medical Schools.—On June 24 Sir Francis Fremantle, Capt. G. S. Elliston, Mr. Messer, and Mr. James Griffiths gave evidence before the Committee on the planning of future medical schools

Notes in Brief

The number of cases of non-pulmonary tuberculosis notified in England and Wales during the year 1941 was 13,720. The number considered to be of bovine origin is not available.

The Public Health (England) (Tb) Regulations, 1942, were presented to Parliament on June 3.

The National Milk Scheme does not affect any powers of medical officers of health in relation to the quality of milk.

Mr. R. A. Butler proposes to ask local education authorities to provide milk and school dinners during the summer holidays. A circular on this and other matters relating to the care of children during the holidays is in course of preparation.

Medical News

Mr. C. Bowdler Henry will deliver a lecture on "The Complications and Treatment of Impacted Wisdom Teeth" at the British Dental Association, 13, Hill Street, W., on July 28 at 3 p.m. All members of the British and Allied Services will be welcome.

The Council of Epsom College have available for orphan daughters of medical practitioners "St. Anne's" Scholarships and "Squire Sprigge" Scholarships. Candidates for the St. Anne's Scholarships must be fully nine years of age, and must be orphan daughters of medical *men* who have been in independent practice in England or Wales for not less than five years. No such restrictions are laid down for the Squire Sprigge scholars. The value of each scholarship is dependent upon the means of the applicant and the locality and fees of the school selected. Forms of application can be obtained from the Secretary's Office, Epsom College, Surrey.

The Ministry of Food announces that a category 1(h) has been added to the schedule of conditions qualifying for priority milk supplies. "Patients with malignant disease, or lymphadenoma, or leukaemia, who are undergoing radiotherapy, whether by means of *x* rays or radium, and who suffer from reactions to the therapy as shown by difficulty in swallowing or digestive disturbances such as anorexia or vomiting," will be entitled to a maximum of two pints daily on the production of the necessary medical certificate, which will be valid for one month, but renewable for two further consecutive periods of one month on the production of further certificates. If another course of treatment is required after an interval, then during this course priority milk will be available to the patient on the same conditions as before. Certificates for priority supplies of eggs or milk for expectant mothers will be valid for three months at a time and renewable for further periods of three months to cover the duration of pregnancy.

The Duchess of Abercorn was present at a crowded meeting, representative of all interests, held in the Whitla Medical Institute, Belfast, on July 3. The Rt. Hon. Sir Hugh O'Neill presided and the meeting was addressed by Dr. Doris Odlum of the Child Guidance Council of Great Britain. At the close it was unanimously and enthusiastically decided to establish a Child Guidance Council for Northern Ireland. The Queen recently allocated a sum of £2,000 from the Bundles for Britain Fund towards this object.

The Association of Scientific Workers, 73, High Holborn, W.C.1 (with the collaboration of the Federation of Ayrshire Scientific Film Societies) has arranged a conference on the scientific film, to be held in two sections: in Ayr on Saturday and Sunday, August 1 and 2, and in London on Sunday, August 16. The aims of this conference are, first, to discuss the need for scientific film societies run by A.Sc.W. branches to give science films the widest possible showing; and, secondly, to draw public attention to these activities and to the need for increased and co-ordinated production of science films.

In view of the shortage of medical specialists, particularly in ear, nose, and throat work, in the south-east of Scotland, the Edinburgh Royal Infirmary has entered into an agreement with the Chalmers Hospital, the Deaconess Hospital, and the Sick Children's Hospital that the out-patient departments of the three last-named hospitals shall be closed and all out-patients will now report to the Royal Infirmary.

The King has appointed Dr. Victor W. T. McGusty, O.B.E., to be a member of the Executive Council of the colony of Fiji for a further period.

EPIDEMIOLOGICAL NOTES

Discussion of Table

There was an increase in the incidence of the majority of infectious diseases in England and Wales during the week; the outstanding increases were 1,206 for measles and 91 for dysentery. The notifications of measles, whooping-cough, and dysentery are the largest weekly totals that have been recorded for 1, 1½, and 4½ years respectively.

Measles

The 7,581 cases of measles notified during the week in England and Wales represent an increase of almost 20% on the total of the preceding week. The largest increases were those in the counties of Yorks West Riding 239, Middlesex 166, Lancashire 152, Essex 149, Surrey 128, Northumberland 94, Hampshire 76, Durham 74, London 70. Decreases were recorded in Kent and Hertfordshire of 79 and 88. The incidence of measles varied considerably throughout the country; in 11 English counties with a low incidence there were only 46 cases, and only a total of 13 in 8 Welsh counties.

For the second consecutive week there was a big decline in the notifications of measles in Scotland, where 358 fewer cases were reported than in the preceding week. In Glasgow 114 cases were notified, a decline of 363.

In Eire 97 cases, an increase of 48, were reported, and in Northern Ireland 233 cases, a decrease of 31.

Dysentery

The largest increase in the notifications of dysentery in England and Wales was due mainly to the outbreak in Cumberland, Penrith U.D.; 100 cases were notified during the week in this outbreak, which started in the preceding week with 31 cases. The only new outbreak of any size occurred in Westmorland, North Westmorland R.D. 14 cases. The largest of the other county totals were those of London 22, Lancashire 16, Surrey 15, Yorks West Riding 15, Oxfordshire 10, and Gloucestershire 10.

Small-pox

The outbreak in Glasgow appears to be effectively checked; no new cases were reported during the 5 days July 11-16. The death of a 72-year-old man brings the death roll to 6. Over half a million persons have been vaccinated, and several of the vaccination centres have been closed. In Swindon several suspected cases have been reported; no deaths have occurred in this town. The medical officer of health has stated that the response to the vaccination offer has been "deplorable."

According to the daily press a mild case of small-pox has been removed to hospital from a ship at Liverpool. The medical officer of health has taken the necessary precautions for dealing with the situation.

Returns for the Week Ending July 11

The notifications of infectious diseases in England and Wales included: scarlet fever 1,279, whooping-cough 1,390, diphtheria 768, measles 7,361, acute pneumonia 625, cerebrospinal fever 87, dysentery 155, paratyphoid 8, typhoid 4.

No. 26

INFECTIOUS DISEASES AND VITAL STATISTICS

We print below a summary of Infectious Diseases and Vital Statistics in the British Isles during the week ended July 4.

Figures of Principal Notifiable Diseases for the week and those for the corresponding week last year, for: (a) England and Wales (London included). (b) London (administrative county). (c) Scotland. (d) Eire. (e) Northern Ireland

Figures of Births and Deaths, and of Deaths recorded under each infectious disease, are for: (a) The 126 great towns in England and Wales (including London). (b) London (administrative county). (c) The 16 principal towns in Scotland (d) The 13 principal towns in Eire. (e) The 10 principal towns in Northern Ireland.

A dash — denotes no cases; a blank space denotes disease not notifiable or no return available.

Disease	1942 (a)	1942 (b)	1942 (c)	1942 (d)	1942 (e)	1941 (Corresponding Week) (a)	1941 (b)	1941 (c)	1941 (d)	1941 (e)

† Owing to evacuation schemes and other movements of population birth and death rates for Northern Ireland are no longer available.

Letters, Notes, and Answers

All communications in regard to editorial business should be addressed to The EDITOR, British Medical Journal, B.M.A. House, Tavistock Square, London, W.C.1.

ORIGINAL ARTICLES AND LETTERS forwarded for publication are understood to be offered to the *British Medical Journal* alone unless the contrary be stated.

Authors desiring REPRINTS should communicate with the Secretary of the Journal Board, B.M.A. House, Tavistock Square, W.C.1, on receipt of proofs. Authors over-seas should indicate on MSS. if reprints are required, as proofs are not sent abroad.

ADVERTISEMENTS should be addressed to the Advertisement Manager (hours 9 a.m. to 5 p.m.). Orders for copies of the *Journal* and subscriptions should be sent to the Secretary.

Telephone No.—B.M.A. and *B.M.J.*: EUSTON 2111.

Telegraphic Addresses.—EDITOR, *Aitiology Westcent, London;* SECRETARY, *Medisecra Westcent, London.*

B.M.A. Scottish Office: 7, Drumsheugh Gardens, Edinburgh

QUERIES AND ANSWERS

Adder Bite

Dr. C. W. **Walker** (Hereford) writes: Having a child under my care suffering from adder bite, I find on looking up the subject very little information as to prognosis. Four or five fatal cases (in this country) are vouched for, and about half a dozen case histories published (Sir T. Oliver's case and Dr. M. R. Taylor's series). I should be most grateful to any doctor who has had this rather rare accident (British adder bite) under his care in the past for information as to the duration of the severe symptoms, and of the subsequent swelling and disability of the bitten limb.

Incidence of Migraine

Dr. M. **Infeld** (London, N.W.6) writes: I am interested in data concerning the frequency of migraine in the United Kingdom. Are there statistics in this regard, official ones or from any out-patient departments?

An Unusual Accident

L. P. S. writes: A cyclist collided with a light horse-drawn vehicle The shaft, about the thickness of the wrist, transfixed the extreme upper part of his thigh and broke off. I was called in to operate 6 hours after the accident. The shaft was *in situ* and entered at the inner side, passed through the centre of the thigh, and the end caused a bulge on the skin on the outer side. An anaesthetic was given and the shaft was pulled out with some difficulty as it was firmly embedded, but there was no resultant haemorrhage. A generous counter-opening was made, the entrance wound was excised, the channel of the wound was cleaned so far as circumstances would permit, sulphanilamide powder was introduced throughout the whole length of the wound, and a through-and-through drainage tube was placed Sulphapyridine—2 tablets every 4 hours—was given subsequently. I was informed that all seemed to be going well until the fifth day, when the whole thigh swelled up from infection and the patient died of septicaemia on the sixth day. Suggestions would be welcomed as to what might be considered the correct treatment of such a case.

Income Tax

Variations in Earnings

P. B.'s earnings in the five years to April, 1942, were respectively £200, £100, £70, £250, and £510. He has *apparently* been assessed for the five years ending April, 1943, on the amounts of £200, £100, £250, £250, and £510. Is this correct?

⁂ It is not possible to say without knowing why the earnings dropped to £70 in 1939-40, but on the face of the figures P. B does not seem to have suffered an excess of tax over the whole period. (A cost-of-living bonus received in cash is liable to income tax.)

Free Quarters as an Officer of the Crown

F is a Civil Servant (prison M O.) with free quarters valued at £50 per annum and is assessed to include tax on that amount. Is this correct?

⁂ Yes. The liability arises under the special rules applicable to Crown property, and the facts accordingly lead to a result different from those where the "occupier" of the whole premises is a private individual, or hospital authority, etc

Diminution in Earned Income

J. M.'s earned income during the actual year ended March 30, 1942, was £750; he has been assessed on £1,250. Has he any remedy?

⁂ Yes. If the aggregate actual earned income is less than the amount as assessed by more than 20% the individual can claim an adjustment of the assessment to the "actual" amount.

LETTERS, NOTES, ETC.

Russian-English Technical Dictionary

Sir John **Russell**, F.R.S. (chairman, Anglo-Soviet Scientific Collaboration Subcommittee) writes: There is an urgent demand at the present time for an up-to-date Russian-English dictionary of scientific and technical terms. It is known that a number of Russian-English glossaries of specific terms have been compiled by various scientific institutions and individuals, and it is thought that it would be extremely helpful to scientists and technical translators if copies of these glossaries could be collected and placed in the Science Library in London, where one complete set could be consulted Will, therefore, any institution or individual who has compiled a glossary of Russian scientific or technical terms, whether printed or in MS., please send a copy to the Secretary of my subcommittee, the British Council, 3, Hanover Street, W.1, who will collect these for the Science Library. It is hoped at a later stage to compile a large dictionary, but the immediate aim is to collect the different glossaries in one place where they can be consulted. Each glossary will be known by the name of its compiler.

Herpes Zoster and Varicella

Dr. F. C. **Gladstone** (Cirencester) writes: Dr. S. L. Brimblecombe's letter (July 11, p. 60) on herpes zoster and varicella raises the interesting question, Should a case of herpes zoster be isolated? As medical officer to a large boys' school I have no hesitation in saying Yes. The following experience will support my contention. Some years ago the head master's children developed varicella, their nurse having had an attack of herpes zoster ten days previously. I had warned the head master what to expect, and as this happened in the holidays we congratulated ourselves that the school had been spared an epidemic of varicella, but this was not to be. One of the boys was allowed to return to school with a mild attack of herpes zoster; his parents had not reported the matter. Although this boy was isolated a few hours after his return, within three weeks the school was enjoying an epidemic of varicella.

Treatment of Scabies

Mr. C. **Klatzkin**, B.Pharm. (Enfield), writes: May I, as a pharmacist, comment on one paragraph of the article on the treatment of scabies by Dr. Kenneth Mellanby, Major C. G. Johnson, and Mr. W. C. Bartley (July 4, p. 1). The authors mention the use of a sulphur vanishing cream. Most vanishing creams are essentially soaps, prepared by the interaction of stearic acid and an alkali; one of the best of these is ammonium stearate. A soap lather and a vanishing cream do not appear to me to be very different For this reason I would not expect a higher percentage of cures in the treatment of scabies to result from the use of a sulphur vanishing cream than from the use of sulphur lather tablets prepared with soap. A formula suggesting this method of preparing sulphur lather tablets was published in the *Pharmaceutical Journal* of Jan. 31, 1942.

Lichen Urticatus

Dr. G. E. **Ellis** (Gillingham, Dorset) writes: About five years ago I wrote a letter to the *Journal* (Nov. 6, 1937, p. 948) to show the remarkable effect upon lichen urticatus of small doses of potassium citrate. No notice was taken of the letter at the time, nor have I seen any reference to the subject since. The seasonal increase of this troublesome condition has now begun, and I should therefore like to bring this simple remedy again to the notice of practitioners, and to urge them to give it a trial Five- to ten-grain doses 3 times a day will clear the greater majority of cases in 3 days

---

MEDICINE 100 YEARS AGO

Extract from the *Provincial Medical Journal* for July 23, 1842:

"The object of the Colleges of Physicians and Surgeons has been defeated. For their own sakes we could have wished that they had been less precipitate—less anxious for their own interests and more ready to sacrifice personal considerations for public good and the benefit of the profession which they affect to represent. Their disappointment, however, may lead to useful results. Defeated in their attempt to obtain fresh powers from the Legislature at the close of the session, the colleges will perhaps be more inclined to listen to the suggestions which emanate from the *real* representatives of the profession; to act with the associations (for we never advocated the destruction of the medical corporations) for the benefit of all, instead of losing their legitimate share of power, by attempting to grasp too much; in a word, to place themselves frankly and openly at the head of the movement, instead of involving themselves in ruin by a useless attempt to divert or disperse a force which they cannot resist."

THE RADICAL SURGERY OF CANCER OF THE LOWER END OF THE COMMON BILE DUCT AND ADJACENT PANCREAS*

BY

GORDON GORDON-TAYLOR, C.B., O.B.E., LL.D., F.R.C.S.

Temporary Surgeon Rear-Admiral

A recent Hunterian Lecture concerned itself, among other problems, with (*a*) the sphincter arrangements of the terminal portion of the bile duct, and (*b*) the radical surgery of cancer in that area. The name of Oddi is often associated with the sphincter mechanism in this region, but an Englishman, Francis Glisson, drew attention to the "ostium with the annular fibres" nearly 250 years before the Italian. The description given by either observer was not an accurate one, and there certainly appears to be no valid reason to attach the name of the physiologist from Perugia permanently to this area. To Glisson at least is due the credit of first directing attention to the ostium, and the name of Glisson's sphincter must at any rate appeal to the patriotic.

Cancer of the caruncula major, the head of the pancreas or its duct, or the peripapillary portion of the duodenum is usually loosely designated "ampullary" carcinoma when surgery is undertaken. Although many cases in the literature purport to be examples of primary carcinoma of the "ampulla," true ampullary cancer must be rare, since this anatomical abnormality is itself infrequent. However, Lieber, Stewart, and Lund (1939) describe an undoubted case: a patient died of obstructive jaundice due to a small polyp arising from the mucosa of a definite ampulla. The new growth infiltrated the surrounding pancreas and muscular wall of the duodenum, but did not implicate the surface epithelium of the intestinal mucous membrane or of the choledochus or pancreatic duct. The specimen was regarded by the Boston surgical authors as an undoubted example of primary cancer of the ampulla.

Lieber, Stewart, and Lund (1939) in their industrious survey of cancer of this area were able to collect only three definite cases of primary carcinoma of the duodenal mucosa covering the caruncula major; the cases had previously been reported by Borelius, Le Noir and Courcoux, and by Countryman. They collected three cases of primary carcinoma of the terminal portion of Wirsung's duct in the literature—those of Letulle and Verliac, of Carnot and Harvier, and of Hadfield.

A very large number of cases of so-called "ampullary" cancer belong to an indeterminate group in which all the epithelial structures of the "papilla" are involved. This early implication of adjacent tissues depends more on the proximity of anatomical structures than upon any special malignancy of the tumour. Such tumours are rarely larger than a hazel-nut, and are said to be limited to the "papilla" in 74% of the patients.

Surgical literature relating to cancer of this region always emphasizes the slow growth and low-grade malignancy of many of the tumours (Outerbridge, etc.). Even in cases in which clinical evidence exists that a carcinoma of the head of the pancreas implicating the bile duct has been present for some time and attained considerable magnitude, mobility of the tumour may still be retained and surgical removal be practicable. In one case of my own, for which three palliative operations (!) of diverse nature had already been performed at another institution during the previous fifteen months and in which the diameter of the tumour was nearly 3½ in., the affected portion of the head of the pancreas was found at necropsy still to retain mobility and showed no involvement of the portal vein or its parent tributaries, and there were no metastases. The hope had been entertained that despite the regrettable wastage of time a radical operation might yet prove possible, but the woman unfortunately succumbed from a mishap during a very minor preliminary operative procedure.

More recently, J. C. Dick (1939) has stressed the low malignancy and the slight tendency to early dissemination exhibited by *tumours of the lowermost end of the common bile duct;* in 11 out of 13 cases at necropsy he found no extension of the tumour beyond the wall of the choledochus, and no secondary growths were demonstrable in glands or other organs. Microscopically, these tumours of the lowermost end of the common duct are adenocarcinomata, composed of irregular acini with large well-formed columnar cells; the cells stain darkly and have well-formed nuclei. There is little evidence of anaplasia, and very few mitotic figures are discernible. The tumour may be a small round, firm, whitish growth of the size of a cherry-stone; it may assume the form of multiple soft vegetations, varying in size from a pea to a hazel-nut. At other times the growth is a diffuse stenosing type, perhaps 1 to 2 cm. long and extending into the head of the pancreas.

Two illustrious American surgeons were the first to perform a resection of the "ampulla." To Halsted (1899) belongs the credit of being the pioneer in 1898, although his patients lived for only nine months after operation; William Mayo (1909) performed the second successful removal of an ampullary cancer in 1900, his patient surviving two years.

The end-results of even minor radical surgery for cancer of the caruncula major are naturally more hopeful than those of palliative measures. Of 7 patients submitted to transduodenal resection at the Mayo Clinic 5 recovered, and the average postoperative survival was nearly 26 months, whereas prospective survival after palliative measures amounted to only 14 months. The numbers of radical operations of varying degree for cancer of this region have slowly and steadily increased, so that Whipple, Parsons, and Mullins (1935) were able to report 80 cases of resection, mostly of limited scope.

Nevertheless, even after limited transduodenal removal some remarkably prolonged survivals have been reported: thus Körte's patient was alive and well 22 years after a transduodenal resection of an ampullary carcinoma; and Schloffer's cases, reported by Clar of Prague, survived 15 years. Kelly's patient was well 9 years after operation, and Cabot's survived 8 years. Lewis had a case of 8½ years' survival, and Oehler had one of 6 years' good health; Lauwers had two successful cases, one surviving 4 years.

---

* Part I of a Hunterian Lecture delivered at the Royal College of Surgeons of England, June 18, 1942.

4256

Involvement of the surrounding pancreas and adjacent tissues demands an increased range of operation if extirpation is to be effective for the more extensive and infiltrative lesions. The value of the two-stage operation in cases of prolonged jaundice has now been learned, and the pre-operative measures directed towards the improvement of liver function and the control of haemorrhage have emboldened surgical effort; experimental work has demonstrated that the external secretion of the pancreas is no longer to be reckoned as indispensable in the digestive economy. The pioneer work of Allen Whipple and his colleagues at the Presbyterian Hospital, New York, demonstrated incontrovertibly the possibility of a truly radical operation for cancer of the "ampullary" region, and the successful results of subsequent operations by these pioneers and by some few other surgeons on each side of the Atlantic have put the operation upon the surgical map. Although the first success to attend a "radical" removal of cancer of the pancreas occurred in 1935, Maingot (1941) states that up to December, 1941, there had been published only 15 radical two-stage resections, including the second part of the duodenum, a variable amount of the head of the pancreas, and even the neck of that organ. Five of these 15 patients died almost outright from the operation; in another promising case (Illingworth, 1939) death occurred from biliary peritonitis more than 6 weeks after operation; two patients died at later dates from the effects of contraction of the surgical stoma between the biliary tract and digestive tube, and three developed subsequent metastases. Thus of the 15 recorded cases collected by Maingot (1941) in only 4 instances were the patients alive at the time of publication of that author's paper.

This Hunterian Lecture affords me the opportunity of adding some personal cases in which at least immediate success has attended limited transduodenal and transcholedochal removal and the more radical extirpation performed according to the Whipple technique; some cases have enjoyed a more prolonged survival. I also include one or two published and some hitherto unpublished cases belonging to my surgical friends.

Transduodenal Resection (2 Personal Cases)

A few years ago, in a discussion at the Meeting of the Association of Surgeons of Great Britain and Ireland held in London, I made mention of two successful cases, in which very early in my surgical career I performed transduodenal resection of a small malignant tumour of the caruncula major. In the course of operations upon two jaundiced patients the tumour felt through the duodenal wall was erroneously thought to be an irremovably impacted calculus, and the duodenal segment of the bile duct was therefore approached through the gut. In each case the tumour was only crudely removed by means of a curved pair of scissors, and the anterior wall of the duodenum sutured; each of the tumours was reported as a short columnar-celled carcinoma.

In the *first case* of the two, the patient, a woman of about 50, operated upon as far back as 1909, died of jaundice and palpable liver metastases two and a half years later, leaving no doubt as to the accuracy of the pathological report.

The *second patient*, treated in a similar amateur fashion, operated upon in 1911, was alive at the beginning of the last war, in 1914, but she was then lost sight of; three years of freedom from recurrence had elapsed since her operation.

Transcholedochal Removal of Tumours of Lower End of Common Bile Duct

Case 3.—A lady aged 55 was operated upon for persistent painless jaundice in 1925. Exploration of a greatly distended common duct revealed several small papillomatous outgrowths within the duct and a larger more sessile tumour obstructing the lumen of the canal almost at its lowermost end. This terminal portion of the duct was exposed and opened by a retroduodenal approach; the tumours were removed locally, the patency of the ostium and permeability of the duct demonstrated, and both openings in the choledochus closed. An anastomosis was effected between gall-bladder and stomach; a drain was left in Morison's pouch. Despite a favourable histological report, signs of pyloric obstruction supervened some months later, necessitating a palliative gastro-jejunostomy. A mass was present in the head of the pancreas which left little doubt as to its nature. The patient died about a year after the primary intervention with all the evidences of malignancy in the abdomen.

Radical Excision of "Ampulla" with Part of Duodenum and Pancreas

Case 4 (Fig. 1): Man aged 60; Painless Jaundice 5 Weeks; Distended Gall-bladder; Ampullary Carcinoma; Death.—Cholecysto-gastrostomy; gastro-jejunostomy; division of first part of duodenum; radical removal with reimplantation of ducts. Most unwisely this operation was performed in one stage; oliguria and subsequently anuria developed, and death ensued in 5 days. The suture lines were in satisfactory condition.

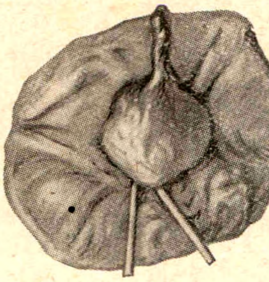

FIG. 1

Case 5: Man aged 58; 9 Weeks' Painless Jaundice; Distended Gall-bladder; Operation June, 1939; Ampullary Carcinoma.—*First operation:* Small bowel divided and united En-Y. Anastomosis between distended gall-bladder and short limb of Y-shaped jejunal junction. *Second operation:* Six weeks later a posterior gastro-jejunostomy was performed, care being taken that the apposed jejunal coil was distal to that segment of bowel with which the gall-bladder was connected, lest an anastomotic ulcer should result. The duodenum was divided and the gastric end inverted; the commencement of the third portion was similarly treated, and the descending duodenum and adjacent pancreas were removed, the common bile duct and pancreatic duct being each ligated with silk. The extraperitoneal bare area was drained. The patient recovered, but died in 6 months from hepatic metastases.

Case 6 (Fig. 2): Woman over 60; Painless Jaundice nearly 3 Months; Modern Pre-operative Therapy; Operation, 1940; Two-stage Intervention; Ampullary Carcinoma.—*First operation:* Cholecysto-gastrostomy. *Second operation:* Six weeks later, posterior gastro-jejunostomy. Removal of descending duodenum with adjacent head of pancreas. Common bile duct and pancreatic duct ligated with silk. Drainage of bare retroperitoneal space. Pancreatic juice leaked in small quantities for several weeks; ultimately ceased. Patient is well 1 year and 9 months later.

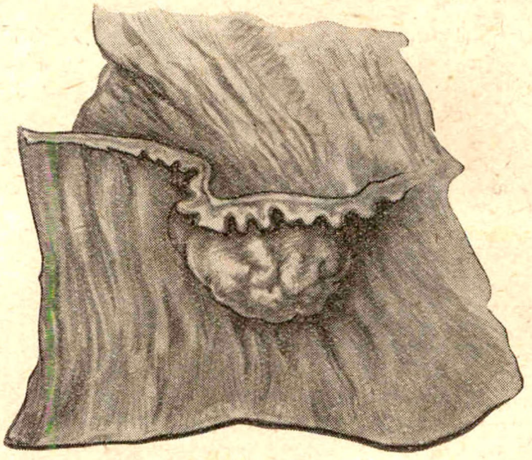

FIG. 2

Case 7: I have previously recorded a successful excision of a carcinoma of the *body of the pancreas* (Gordon-Taylor, 1934). At the operation, performed in July, 1927, a mass was removed one and a half times the size of the closed fist. The tumour was reported upon by Prof. S. Baker, now of Manchester University, as a columnar-celled carcinoma; an enlarged lymphatic gland attached to the mass was not infected with growth. The splenic artery required wide excision since it was implicated in the tumour mass; in addition to the removal of a length of the upper circumference of the expanded splenic vein, the left half of the commencement of the portal vein also required ablation. The operation was laborious, and at its termination only that part of the pancreas embraced by the concavity of the duodenum appeared to remain. No subsequent sequela referable to the spleen made me regret the decision to conserve that organ, despite the surgical interference with both its arterial and its venous blood supply. The patient continued in excellent health until the autumn of 1938—that is, 11 years—when the possibility of a recurrence suggested itself. *Just over 13 years after the removal of the tumour* he died from undoubted abdominal malignancy—probably a late metastasis of the original tumour.

Case 8 · A Calcified Mass embedded in the Pancreas and compressing the Common Bile Duct; Removal of Mass together with Portion of Head of Pancreas.—A stoker 49 years of age with jaundice of 4 months' duration; rather poor physique. Two-stage operation after modern pre-operative measures. *Cholecysto-gastrostomy*; at operation a firm mass was palpated in the head of the pancreas near the ampulla, and was regarded as confirmatory of the accuracy of the pre-operative diagnosis of ampullary cancer. *Second operation*, undertaken 6 weeks later: The second part of the duodenum was mobilized and the mass approached from behind. The tumour was found embedded in the substance of the head of the pancreas in intimate proximity to the retroduodenal and pancreatic portion of the common duct, and was removed from the pancreas with some of the gland tissue. On section the tumour was found to consist largely of calcareous material, possibly a mass of agminated calcified tuberculous glands. There was perhaps some justification for the mistake in diagnosis, but at least the patient is to be congratulated on the pathological nature of the compressing mechanism, which before this experience I might have seriously doubted.

Prof. C. F. W. Illingworth has had two admirable unpublished cases in which a successful radical two-stage operation for cancer of the pancreatic head was performed, and which I had the good fortune to see in Glasgow some months ago. My friend Victor Hurley of Melbourne told me that he had successfully removed a malignant tumour from the head of the pancreas by a retroduodenal approach, without removing the duodenum or bile duct. Rodney Maingot's (1941) excellent case is the first truly radical and successful case to be reported in Britain.

Some new growths of the ampullary region are apparently radiosensitive. Upcott (1935) performed a local excision of an ampullary growth and introduced radium on a probe down the common duct; the patient was well *15 years later.* Sampson Handley (quoted by Upcott, 1935), employing 6 mg. of radium for 5 days, was able to report 3 cases free from recurrences for 10 months, 2 years, and *14 years*, respectively. Sir James Walton (1939a) reported two successful cases of resection of the common bile duct for cancer in his Bradshaw Lecture of 1939, but amid the wealth of surgical experience and skill contained in this address these two cases deserve special mention lest they escape notice. Mr. C. E. Kindersley of Bath had also a successful case of resection of the junction of the cystic and common bile duct; this patient has survived several years.

Of *transduodenal resection of the duodenal end* of the common bile duct, my friend Mr. David Ligat of Hastings, operating at Middlesex Hospital in 1916 during the last war, had a successful case, the patient living *nearly five years* before ultimately dying of obvious malignant recurrence in the liver. This man had been jaundiced for 4 or 5 months, and the extrahepatic ducts were enormous.

These cases have been reported in the hope that the younger generation of surgeons may be encouraged to attempt to cure and not merely to palliate. The natural history of ampullary and pancreatic tumours justifies more vigorous surgical effort, and the end-results of the cancer surgery of this region should compensate the operator for his enterprise.

The concluding part of the Lecture will appear, with a list of references, in next week's issue.

The plan for fusion recommended by the Council of the Incorporated Association of Hospital Officers and of the Incorporated Association of Clerks and Stewards of Mental Hospitals has been adopted by extraordinary general meetings of both associations. Accordingly, from Oct. 1 next the two bodies will be amalgamated under the title of the Incorporated Association of Hospital Administrators, and membership will be open to all duly qualified lay hospital administrators.

DIPHTHERIA IMMUNIZATION OF ADULTS

BY

H. MASON LEETE, M.D., D.P.H.

Medical Superintendent, Hull City Hospital, Cottingham

The admirable paper by Fulton *et al.* (1942) has, with convincing proof, laid down a highly efficient routine for the immunization of children with alum-precipitated toxoid (A.P.T.). The dosage of 0.2 c.cm. followed by a second dose of 0.5 c.cm. at an interval of not less than 4 weeks has received the approval of the Chief Medical Officer to the Ministry of Health in his letter to all medical officers of health dated May 8, 1942. It is safe to assume that such a method will become routine and will at last lead to satisfactory immunization in this country. Provided we can rely on the antigen, the checking of which is the concern of the issuing and controlling laboratories, we now have an efficient and simplified diphtheria prophylaxis. Schick-testing can be dispensed with and records can be reduced to the insertion of a batch number and two dates upon a card. Whether this work be done in a consulting-room, a child welfare clinic, or a school will matter little. The aim now should be to get over 80% of children under 10 years of age treated in this manner.

At the same time the Chief Medical Officer to the Ministry, in another letter, advised that nurses in general hospitals who are Schick-positive should be immunized with toxoid-antitoxin floccules (T.A.F.), 3 doses of 1 c.cm. being injected at intervals of 3 weeks. The reason given for this recommendation is that T.A.F. tends to give rise to less reaction than does A.P.T.

Fulton *et al.* in their paper state that above the age of 18 years the number of subjects tested (20) was too small to enable them to obtain a reliable figure for the Schick-conversion rate. This encourages me to add as a small contribution the figures I have collected during the past 9 years in the course of immunizing the staff at the Hull City Hospital. Though not large they have been carefully compiled, and all testing, readings, and injections have been done personally. All persons in the group are more than 16 years of age, and the great majority between 18 and 20. Most are nursing and domestic staff at the hospital, but occasional visitors, medical and otherwise, have been included.

After various experiences with other antigens since 1922, including T.A.M. and F.T., I began to use T.A.F. in 1933, giving 3 injections at monthly intervals and Schick-retesting 4 weeks after the last dose. The Schick-conversion rate was not good, and largely for this reason I turned to A.P.T. in March, 1935, giving 0.3 c.cm., followed after 4 weeks or a little longer by 0.3 c.cm., with a Schick-retest one month later. Originally I had intended to give 0.25 c.cm. and 0.25 c.cm., but there was always enough in a 0.5-c.cm. ampoule to give two doses of 0.3 c.cm. to two subjects, so it seemed a pity to waste antigen. The Schick-conversion rate rose to 100%. I get no severe reactions, and the method, except for an increase to 0.5 c.cm. for both doses in 1940, has been in use since. In 1936 I began to give a single dose of 0.3 c.cm. of A.P.T. to Schick-negative reactors if they did not have a pseudo-reaction, and have continued that procedure, increasing the dose to 0.5 c.cm. in 1940. The results are summarized in Table I. The details given in this Table suggest that the T.A.F. used in 1933 was a weak antigen and that it was considerably improved in the following year. Despite this improvement, the T.A.F. results as a whole were poor (Schick-conversion rate 78%). The excellent results with A.P.T. were so soon apparent that there was no question of return to the older antigen. I would regard any such return as a regression.

Reactions

There were no severe reactions in any of the 388 adults immunized. I have notes of only 5 moderate local reactions —4 with A.P.T. and 1 with T.A.F. One of the 4 A.P.T. reactors was a pseudo-negative who was given 0.1 c.cm. of A.P.T. as a detector dose. Some local reactions have doubtless

TABLE I.—*Diphtheria Immunization of Adults at Hull City Hospital, Cottingham*

Year	Schick		No. Immunized and Retested	Antigen	Schick Retests		No. originally Schick-neg. given 1 dose A.P.T.
	Neg.	Pos.			Neg.	Pos.	
1933	44	47	32	1 c.cm. T.A.F. 4 weeks	19	13	
1934	59	36	27	1 c.cm. T.A.F 4 weeks	26	1

1937	37	41	36	0 3 c.cm. A.P.T. 4 weeks	36	0	24 „
1938	60	23	18	0.3 c.cm. A P.T.	18	0	43 „
1939	44	26	25		25	0	36 „
1940	51	24	15		15	0	27 „
			5	0.5 c.cm. A.P.T. 4 weeks	5	0	18 (0.5 c.cm.)
1941	35	15	11	0.5 c.cm. A.P.T.	11	0	25 „
	387	261	210	T.A.F.: 63 A.P.T.: 147	49 147	14 0	— 178

occurred and not been reported; anything severe would have been. No time off duty has been lost owing to reaction and nothing has required treatment.

In this connexion it might be as well to add that the skin was cleansed with ether on a small swab, both injections were made into the triceps of the left arm, the syringes were all-glass 1 c.cm. dry (hot-air) sterilized, and the stainless-steel needles for injection were of the same small type as that used for the Schick test. The needles were also hot-air-sterilized. Each dose was given from a sealed glass ampoule opened at the time. The syringes are kept for the one purpose sterile in Petri dishes. All antigens employed were "Wellcome" products as ordinarily issued.

When persons are immunized with T.A.F. they are rendered serum-sensitive in consequence of the antitoxin fraction in the antigen. It is difficult to assess the degree of such sensitization, but I have noted in 2 cases that nurses who had received T.A.F. had greatly accentuated serum sickness, amounting almost to anaphylactic phenomena, when given therapeutic sera months after their immunization. Since the introduction of refined (protein-digest) therapeutic sera almost the only cases of serum sickness I see in hospital are in children who have been immunized with T.A.F. Is not the presence of an antitoxin fraction in any material for active immunization an anomaly? With the remarkable results now obtained with A.P.T. surely we may say that the weaker antitoxin-containing antigens are becoming obsolete.

Subjects who are most likely to have severe reactions are those who give pseudo-negative reactions to the Schick test. I have not as a rule given a "reinforcing" dose of A.P.T. to such subjects. These pseudo-negatives are, however, excellent material for testing reactions, and 6 of my nursing staff who fall into this group kindly offered themselves as experimental animals. They were injected in the left arm, using the usual technique, with 0.1 c.cm. of A.P.T., and in the right arm with 0.1 c.cm. of T.A.F. They were closely observed at 12, 24, and 48 hours, and at 3 and 7 days. General and local reactions were most marked at between 36 and 48 hours; the visible signs were most obvious at 48 hours, after which, except in 2 cases, they began to subside. The results are summarized in Table II.

TABLE II.—*Experimental Test of T.A.F. (Right Arm) and A.P.T. (Left Arm) on Sensitive (Schick-pseudo-negative) Subjects*

Subject	Hours after Inoc.	Headache	Malaise	Temp.	Pain		Tenderness		Redness		Induration

R = right arm. L = left arm. ± = very slight. + = slight. ++ = moderate. s = stiffness rather than pain. The long diameter of redness is shown in mm.

The 7-day readings were as follows: A, D, E—small painless nodules in left arm only; B, F—induration and sterile abscess in left arm; C—small painless nodule in left arm; slight right axillary adenitis.

It will be seen that in 5 out of the 6 cases there was more local reaction with A.P.T. than with T.A.F. In 4 subjects local signs were subsiding by the third day, except that the left arms had the small nodule of infiltration that is usual with this antigen. Three of the reactions could be classed as moderately severe. All were feeling well by the third day despite their local signs. No member was off duty; in 2 subjects the headaches were severe enough to need acetyl-salicylic acid. Two volunteered the statement that their "worst" arms were not so bad as when they had had anti-enteric vaccine, and the others when asked about this stated quite definitely that that was their experience also. It must be noted that the dose of A.P.T. was an effective immunizing one, while that of the T.A.F. was a tenth of the recommended dose.

At 7 days 3 had nodules in the left arm without pain or tenderness, but 3 presented definite signs, of which more must be said. Subjects B and C were very sensitive. At 36 hours B had to keep her arms folded to minimize axillary pain, which was similar on both sides. At 48 hours the redness of the left arm showed double zoning with approximate diameters of 30 mm. for the inner zone and 80 mm. for the outer; but she felt much better generally than 12 hours previously. She was able to use her arms quite comfortably at 3 days. At 7 days the left arm still showed moderate induration and swelling. There was a superficial abscess from which 2 to 3 c.cm. of pus was withdrawn by aspiration. Culture on blood-agar plate and into infusion broth gave no growth.

Subject C was the only one who showed more reaction with T.A.F. than with A.P.T. She had general symptoms, headache, shivering, and a feeling of sickness at 48 hours, and did not eat her breakfast. At 48 hours both arms were equally tender, although there was much more swelling and redness on the right. At 7 days, on the right side there was slight axillary adenitis but no pain or tenderness at the injection site, on the left side a small nodule at the site without pain or tenderness. This nurse had reacted markedly to anti-enteric vaccines in March, 1941, was in bed and off duty for a day then, and volunteered the statement that her arm was much worse than either was now. She affords an excellent example of what I believe to be generally true, that it is the individual rather than the antigen or its dose that is the chief factor in these reaction phenomena.

Subject F, though her symptoms were not so pronounced during the first 3 days, showed redness, tenderness, induration, and sterile abscess formation in the left arm at 7 days. Two or three c.cm. of pus was aspirated, and this gave no growth when inoculated into broth and on to a blood-agar plate. There was no pain, local or axillary, and no adenitis. On the eleventh day a small incision was made and about 20 c.cm. of pus evacuated.

Discussion

My impression in reviewing these experimental tests is that I have been right in not giving A.P.T. to pseudo-reactors. Until now I have never seen sterile abscess formation, though I was aware it had been reported. Such cases were probably similar to these—pseudo-reactors who had been given A.P.T.: the remedy is, not to use T.A.F., which will give a strong though in most cases a lesser reaction, but not to immunize pseudo-reactors at all. Here I must plead for a careful reading of the Schick tests: the arms must be seen at 24 hours and at 7 days by one who has had some experience of reading the reaction; otherwise pseudo-reactors will be read as positive, and results obtained similar to those in this short experimental series, to the discredit of the antigen when it is the selection of the individual that is at fault. I have notes on a subject who was repeatedly and painfully immunized with T.A.F. because of so-called positive reactions; at last, failing to get a "negative," a blood antitoxin titration revealed the presence of between 5 and 10 units of antitoxin per c.cm.! It is an important though secondary function of the Schick test to detect these sensitive persons, and for this reason the test with control should not be omitted in the older groups.

It is probable that all pseudo-reactors are Schick-negative. I have never seen, at any rate in an adult, an undoubted combined or pseudo-positive reaction. In a series of 51 pseudo-reactors 48 were definite pseudo-negatives, and in 3 I queried the possibility of the reading being a combined one.

Conclusion

As a result of this experience with A.P.T. covering several years, and on consideration of the experimental tests detailed, I would suggest that nurses can be immunized with that antigen without undue risk of reaction. The one thing to guard against is the unnecessary immunization of pseudo-reactors. I am inclined to think, in view of what Fulton *et al.* say, together with my own experience of 0.3-c.cm. doses, that an initial dose of 0.5 c.cm. is not necessary. Schick-positive adults will be efficiently immunized, where it is considered desirable to do so, by giving 0.2 c.cm. and 0.5 c.cm. of A.P.T. with a four-weeks interval. In other words, one method, the efficiency of which has been proved beyond doubt, should be used for both children and adults.

DIPHTHERIA IMMUNIZATION IN A METROPOLITAN BOROUGH

BY

V. FREEMAN, M.R.C.S., D.P.H.
Medical Officer of Health, Islington

Until very recently London as a whole held an unenviable record as compared with some provincial towns and cities in the matter of diphtheria immunization. Hence there are comparatively few figures available of reasonably large-scale analyses of the state of natural immunity as shown by the Schick test of the child population in the various parts of London—which might be expected to exhibit their own peculiarities—and of the various responses to different immunizing agents. It was therefore considered that some recent figures relating to a large and fairly representative London borough might be of special interest.

In the early part of 1937 an immunization scheme was started, based on the following principles: (1) Immunization of children 7 years of age and under with alum-precipitated toxoid (A.P.T.) in 2 doses. (2) Immunization of children over this age (except in a few special cases) with toxoid-antitoxin floccules (T.A.F.) in 3 doses. (3) Primary Schick tests for children of 7 years and upwards. (4) Post-Schick tests for all immunized cases. These particular methods were adopted in the light of local factors which made it especially desirable that the number of immunizing attendances should be reduced so far as was possible, but bearing in mind also that reactions following injection should be at an absolute minimum and that the immunizing process should have a very high degree of effectiveness.

The progress of diphtheria immunization was completely suspended for the early part of the war. Figures for the last complete pre-war year, 1938, and for the first full war year, 1941, have been analysed, and their results are as follows.

Primary Schick-test Rates

Islington is a densely populated borough (acreage 3,092; Registrar-General's estimated population, mid-1938—292,300), with the greatest density in the south and south-west. It was not practicable, for the purpose of this analysis, to separate children living in different parts of the borough. The figures given are for girls and boys, and do not include children with a previous history of diphtheria or of diphtheria immunization.

It will be noted that the average Schick-positive rates for 1938 and 1941 approximate each other very closely, and are considerably lower than those given by Wilson and others (Fulton *et al.*, 1942) for Oxfordshire, etc. (77.9%, excluding children under 5 years), and Lewis (1941) for Croydon (76.4%). It will also be noted that although at 5 years the Schick-positive rate for 1941 does not differ greatly from Wilson's (85.5%), the decrease during school years as shown in Table I is very much more rapid, the rate standing at a little over 40% for Islington at 14 years, but still at the high figure of 70.4% for the counties. The rates in Table I, however, approximate rather more closely to those given by Lewis for schools of high diphtheria incidence, and in this connexion it may be stated that the diphtheria incidence in 1938 for this borough was about 7 per 1,000 school children and 8 per 1,000 children from 1 to 15 years of age.

TABLE I

Age (Years)	Children Tested in 1938			Children Tested in 1941		
	No. Tested	No. Positive	% Positive	No. Tested	No. Positive	% Positive
5 & 6	11	6	54·5	283	250	88·3
7	31	24	77·4	233	186	79·8
8	80	59	73·8	217	170	78·4
9	81	60	74·0	319	220	68·9
10	87	53	60·9	306	187	61 1
11	69	45	65·2	292	193	66·1
12	32	14	43·75	313	155	49·5

14	18	8	44·5	206	85	41·7
Totals..	437	285	65·2	2,425	1,568	64·7

The anomalies in some of the age groups, particularly the 5- and 6-year-olds in 1938, are obviously due to the small numbers in these groups.

For purposes of comparison with other boroughs I have included the figures for Kensington and for Heston and Isleworth (Table II), for which figures I am indebted to Dr. Bousfield, and also to Dr. Anderson, medical officer of health, Heston and Isleworth, and to Dr. Fenton, medical officer of health, Kensington. Since the Kensington work and a good deal of the Heston and Isleworth work were both done by Dr. Bousfield, individual differences should not affect the figures.

TABLE II.—*Primary Schick-test Rates (1941)*

Age (Years)	Kensington			Heston and Isleworth

Results of Immunization by A.P.T. and T.A.F.

Although A.P.T. for children under 7 years and T.A.F. for children over 7 years were the immunizing agents of choice, there were some slight differences in dosage for the years 1938 and 1941, respectively.

TABLE III

	A.P.T. Dosage			T.A.F. Dosage			
	1st	2nd	Interval	1st	2nd	3rd	Interval
1938 ..	0 1 c.cm.	0·5 c.cm.	2 weeks	1 c.cm.	1 c.cm.	1·2 c.cm	2 weeks
1941 ..	0 2 c.cm.	0 5 c.cm.	2 ,,	1 c.cm.	1 c cm.	1·5 c.cm.	2 ,,

A.P.T. for 1938 and for 1941 were not obtained from the same sources, but T.A.F. was supplied by the same firm throughout.

The great majority of the post-Schick tests were performed between the thirteenth and twentieth weeks after the final immunizing injection. All Schick tests are read on the seventh day.

TABLE IV.—*Rates for 1938*

	No Primary Schick	Primary Schick-positive	No. Positive after Immunizing	Schick-conversion Rate	Schick-negative Rate
Immunized with A.P.T.	—	227	10	95 6%	—
	551	—	5	—	99·1%
Immunized with T.A.F. .	—	23	2	91·3%	—

TABLE V.—*Rates for 1941*

Age (Years)	Immunized with A.P.T.				Immunized with T.A F	
	No Primary Schick	Positive after Immunizing	Primary Schick-positive	Positive after Immunizing	All Primary Positive	Positive after Immunizing
1	184					
2	275	2				
3	205	1	1			
4	180	1	3			
5	143	1	55		1	
6	70		132		4	
7	36	1	141	1	10	
8	15		88	1	41	
9	6		24	1	135	
10	2		7		134	
11	4				132	2
12	1				119	1
13					97	
14					43	
	1,121	6	451	3	716	3
	Schick-neg. rate 99·5%		Schick-conversion rate 99·3%		Schick-conversion rate 99·6%	

The above results compare very well with the most favourable ones obtained by other investigators, both for A.P.T. and for T.A.F. Published results for A.P.T. were recently summarized in tabular form (Fulton *et al.*, 1942).

Discussion

I. Dosage Interval

Although laboratory immunological considerations appear to favour a four-weekly or greater interval between doses, it is felt that in some districts mothers are more likely to bring their children for completion of immunization if the interval between doses is as short as possible, and that fortnightly appointments are much more likely to be kept than monthly ones. This is particularly important with children up to 5 who are not under school or nursery control or in residential institutions. Bousfield has stressed this point. If with suitable antigen Schick-negative or Schick-conversion rates of over 99% can be obtained, there would appear to be no valid objection in practice to a fortnightly interval between injections beyond the unconfirmed possibility of a higher relapse rate at a later stage. When results of this order are obtained with a short interval, the evidence that the same antigen when given at longer intervals in comparable cases will materially affect the respective Schick-relapse rates must for the present be considered inconclusive.

II. Primary Schick Test

The age of 7 years was arbitrarily chosen some time ago, pending the collection of further data on the Schick state of the child population locally, as a period when the proportion of Schick-negatives might show signs of rising appreciably. The Schick tests performed so far indicate, as summarized in Table I, that the proportion of Schick-negatives rises to about one-third at over 9 years of age.

Lewis states: "It has been calculated that when the probable number of Schick-negative reactions is 25% . . . then it will mean considerable extra time, much inconvenience, and the unnecessary use of prophylactic, if wholesale inoculation is carried out, irrespective of immunity state." Lewis does not mention the basis of this calculation, but if we consider the problem only as it affects attendances, and assuming that two-dose A.P.T. is the immunizing agent and a post-Schick test is done in every case, then out of every 100 cases, if 33 are primary negative and the remainder positive, 67 will make 5 attendances each—amounting to 335—and 33 will make 2 attendances each—amounting to 66; giving a total of 401 attendances. If no primary Schick test is performed, then 100 cases will make 4 attendances each—that is, 400 attendances. Accordingly, if the primary Schick-negative rate rises above 33% there will be a saving on attendances, but not otherwise, on the above assumptions for immunizing procedure.

From this point of view, therefore, primary Schick-testing may be dispensed with if the Schick-positives are likely to be more than two-thirds of the total group, or below the age of 9 years if the rates determined in Table I are applicable to other areas. If no primary tests are performed above this age there will be unnecessary attendances, and material used, in increasing proportions as the age groups rise.

The above factors deal only with considerations of mass immunization. From the point of view of the individual parent or the child to be immunized, it might be preferable to be given a 1 in 4 or even 1 in 5 chance of not undergoing a complete immunizing course with a possible post-Schick later on.

A further advantage of performing primary Schick tests for higher age groups is that arising from Wilson's conclusion that Schick-negative children of any age, or Schick-positive children of 10 years of age or over, may respond to A.P.T. with severe reactions. This point must be given particular emphasis where there is a high proportion of Schick-negative reactors among the older age groups at school, such as is shown in Table I, and where such consequences, occurring in considerable numbers, would tend to discourage a mass-immunization campaign. A primary Schick test therefore has the additional advantage of selecting the most probable A.P.T. reactors.

III. Post-Schick Tests

It may appear unnecessary, once preliminary investigations have established satisfactory results, to continue post-Schick testing when the Schick-negative and conversion rates are in the region of 99%. Batches of antigens may differ considerably in their immunizing powers, however, and post-Schick sampling therefore seems necessary as a minimal precautionary measure. Further investigation appears desirable as to the optimum proportion which should be sampled, so that poor batches may be detected with reasonable certainty at an early stage. It would not be an easy matter at the present time in some parts of London to recall children in satisfactory numbers for further immunization three, four, or five months after their original immunization with a poor immunizing agent. Provided that time, staff, and material are available, and until antigen variability per unit volume is eliminated, it would seem a safer procedure to post-Schick-test all those immunized. Otherwise, risks are run which must be recognized.

IV. Immunization with T.A.F.

Very satisfactory Schick-conversion rates have been effected with T.A.F. for older children. The administration of 1 c.cm., 1 c.cm., and 1.5 c.cm. was made consequent upon observations by Bousfield, using a variation of the final dose. No single moderate or severe local or general reaction has been reported, and in only a very few instances was the medical officer informed at the following clinic that after the previous attendance there had been a little local tenderness around the site of injection but with no subsequent physical signs.

It cannot perhaps be said that the use of T.A.F. is absolutely necessary for older children, but it is a very satisfactory antigen to use. Wilson and his co-workers note that severe reactions with A.P.T. will be more frequently encountered in Schick-positive children of 10 years of age or over, and that 42% of Schick-positives showed some degree of local reaction to A.P.T. Lewis mentions that when the primary dose of A.P.T. causes a reaction it might be wiser to withhold the second injection of A.P.T. and substitute three T.A.F. injections of 1 c.cm. each. Such a procedure would appear likely to substitute four immunizing injections in a considerable number of older children in place of the two originally planned, and these children would also have experienced the discomfort of a reaction.

If it is particularly desired to avoid reactions in older children it is suggested that T.A.F. as a routine immunizing agent might be restricted to children over 10 years of age.

Summary

A series of children in a London borough from 1 to 15 years of age were immunized and in part primary Schick-tested. The results for two recent complete years, 1938 and 1941, have been given.

Of 437 children of school age tested in 1938, 65.2% were primary Schick-positive. The corresponding numbers for 1941 were 64.7% positive out of 2,425. Over four-fifths of the children were positive at school-entry age, but only a little over two-fifths were found positive at school-leaving age.

A.P.T. given in doses of 0.1 c.cm. and 0.5 c.cm. with a fortnight's interval produced a Schick-conversion rate of 95.6% and a Schick-negative rate of 99.1%. A.P.T. similarly administered in doses of 0.2 c.cm. and 0.5 c.cm. gave a Schick-conversion rate of 99.3% and a Schick-negative rate of 99.5%. T.A.F. given in three fortnightly doses of 1 c.cm., 1 c.cm., and 1.2 c.cm. produced a Schick-conversion rate of 91.3% (23 cases only), and in fortnightly doses of 1 c.cm., 1 c.cm., 1.5 c.cm., a Schick-conversion rate of 99.6%.

Provided a suitable antigen is given in appropriate doses, no practical immunological disadvantage is apparent if an interval of two weeks between doses is employed because it is administratively advantageous locally instead of four weeks.

With A.P.T. in two doses as the antigen, clinic visits will be saved if primary Schick tests are performed in all cases when the expectation of natural immunes is more than one-third of the total for the age groups concerned. In a typical London borough this can be expected from the age of 9 years onwards. The selection of the primary Schick-negatives when they form a considerable proportion of all children also assists in eliminating or indicating (if it is desired to give a single safeguarding injection) the most probable sufferers of local reactions to A.P.T.

In view of the existing variability of the same types of antigens, post-Schick-testing or, as a minimum, post-Schick-sampling is necessary.

Diphtheria immunization clinic work for 1938 was carried out by the author, and for parts of the year by Drs. D. S. Murray and K. M. Hirst. The bulk of the 1941 clinic work was done by Dr. H. W. Swann, to whom appreciation is due for his careful work and enthusiasm, and the remainder by Dr Mary Adams. Thanks are also due to Mr. D. A. Owen, clerk in the Public Health Department, for his conscientious maintenance of records and clinic arrangements generally. Thanks are also expressed to Drs. Bousfield, Anderson, and Fenton.

PROGNOSTIC VALUE OF THE BLOOD SEDIMENTATION RATE IN PULMONARY TUBERCULOSIS

BY

E. LEWIS-FANNING, Ph.D.
Member of the Statistical Staff of the Medical Research Council

AND

MAURICE MYERS, M.R.C.S., L.R.C.P.
Senior Assistant Medical Officer, Brompton Hospital Sanatorium, Frimley

During the past twenty years the estimation of the sedimentation rate of the red blood corpuscles has gradually become established as part of the routine examination of patients suffering from pulmonary tuberculosis. The test has been thoroughly investigated, and a vast amount of literature describing the results has been published. It is claimed that the test has a definite value as a guide to the reaction of the patient to his disease, and, in brief, it is thought that a rising B.S.R. denotes that the condition of a patient suffering from pulmonary tuberculosis is deteriorating while a steadily falling or consistently normal result indicates that he is improving.

The literature was studied by us with great interest, and for some time the test was performed regularly on all in-patients of this sanatorium, the results being considered in conjunction with serial x-ray films and the usual clinical observations and data. It may be stated at this point that it is our practice to radiograph our patients at monthly intervals, especially during the early months of their treatment. After prolonged investigation we came to the conclusion that while the claims regarding the test were, broadly speaking, true, it was not of great value from the point of view of the hospital or sanatorium physician, whose patients were under close observation, as the test did not give any information which could not be obtained from the usual routine methods and serial x-ray films. Furthermore, the test would have to be performed at regular and frequent intervals on every patient, involving an amount of time and work not commensurate with the value of the information procured. It was also observed that the test was not 100% efficient and that in some cases the results could be misleading. It was possible to observe a patient with obviously progressive disease (as shown by serial x-ray examination) but whose B.S.R. remained unchanged and within normal limits. Conversely, patients with lesions known to have been static over long periods often produced a persistently abnormal B.S.R.

Although these results suggested that the test was not of great value in assessing the progress of patients under institutional conditions, it was thought that it might be of more use when the patient was not in a hospital or sanatorium and in consequence not under such close observation and supervision by his physician. Accordingly the investigation was repeated on the patients attending our out-patient clinics; but again no evidence was obtained that the B.S.R. was superior to the usual examinations in indicating the progress of the disease or evidence of relapse. In addition one was apt to be misled by the alteration in the reading that followed any intercurrent infection which the patient had forgotten or had not thought worthy of mention.

As a result of these investigations we considered that the B.S.R. was of only limited value as an index of progress in a case of pulmonary tuberculosis and could not supersede any of the usual methods of examination. But we had noted that the B.S.R. did alter with the different pathological phases of the disease, and therefore thought it might be worth while to examine the test from a different point of view—namely, from the more remote, as opposed to the immediate, prognosis.

Observations Made

For this purpose B.S.R. estimations were done on admission and on discharge on all patients coming into this sanatorium during a period of nearly 3 years (1936-9). These values were recorded on separate cards for each patient, together with the name, age, sex, date of admission and discharge, the Ministry of Health classification of the state of the disease, the extent of lung involved as disclosed by x-ray examination, and, from the follow-up department of the hospital, the condition of the patient at the latest known date, under the headings "Alive and Working," "Alive," or "Dead."

It will be observed that the data are limited to patients who were discharged, and do not include those dying during their treatment in the sanatorium, for whom only the B.S.R. at entry would be known. But our concern, as stated above, is with the relationship—if any—between the B.S.R. and the state of health subsequent to discharge: the deaths in the sanatorium are for this purpose irrelevant. In all, 630 patients (292 males and 338 females) were discharged between Jan. 1, 1937, and June 30, 1939, their dates of admission lying between Jan. 1, 1936, and June 30, 1939, and their average stay in the sanatorium being 148 days for males and 141 days for females (round these averages there naturally was much variation). These numbers were clearly too small to allow the B.S.R. to be related to the subsequent history of patients of different ages as well as of each sex. Division by sex was clearly necessary, but age, as statistical analysis showed, was not an important factor. In the treatment of the material no differentiation by age has therefore been made. The percentage-age distribution of the patients was, in fact, as follows:

	10—	20—	30—	40—	50+
Males	7	41	33	16	3
Females	18	52	25	4	1

The history of these patients between discharge and the end of April, 1940, was known for variable lengths of time, and it has been analysed in terms of 6-monthly intervals—i.e., the mortality experience in the first 6 months after discharge, in the second 6 months, etc.

Results

An approximate picture of the relation between the B.S.R. at discharge and the subsequent history is given in Table I.

TABLE I

B.S.R. at Discharge	Males		Females	
	No. of Patients	No. Dying after Discharge	No. of Patients	No. Dying after Discharge
0–4 ..	93	0	42	0
5–9	70	0	91	2 (2·2%)
10–29	85	9 (15·9%)	151	5 (3·3%)
30–49	27	7 (25·9%)	32	5 (15·7%)
50 and over	17	9 (52·9%)	22	2 (9·1%)

With males the figures show a clear association between the B.S.R. on leaving the sanatorium and subsequent ability to survive. With the B.S.R. under 10 no deaths at all had occurred in the 163 patients concerned; at 10–29 approximately 1 in 9 of the 85 patients had died; while at 30 or over, 16 of the 44 patients, or approximately 1 in 3, had died. The same trend is apparent with females, though the changes are of a slighter degree. Of the 133 with B.S.R. under 10, 2 (1.5%) had died; at 10–29 the proportion rises to 3.3%, and at 30 and over to 13%.

This method of analysis is rough, since it presumes that the durations of observation for all patients subsequent to discharge do not differ materially between the B.S.R. groups. It seems unlikely that these durations would differ, and a more accurate analysis in which they are taken into account confirms the results of Table I. In this analysis (see Table II) calculation was made of the numbers exposed to risk of dying in each 6-monthly period after discharge,* and, related to the deaths occurring in each such period, it gives a death rate at each point of time for the varying B.S.R. groups.

With the males, it will be seen, there is a consistent rise in mortality with increasing B.S.R. above 10 (i.e., at discharge) at each 6-monthly period after discharge. For instance, in the first 6 months after leaving the sanatorium the percentage death rates are 0 at B.S.R. 0–4, 0 at B.S.R. 5–9, 3.6 at B.S.R. 10–29, 7.5 at B.S.R. 30–49, and 18.8 at B.S.R. 50 and over. Similar changes are apparent up to 18 months after discharge, beyond which point the numbers at risk become too few to be of very much value. With the females there is clearly a suggestion of a similar trend, but the figures are not nearly so consistent. For instance, in the period 6–12 months after discharge the percentage mortality runs 0 at B.S.R. 0–4, 1.4 at B.S.R. 5–9, 0.8 at B.S.R. 10–29, 4.3 at B.S.R. 30–49, and 6.3 at B.S.R. 50 and over. At 12–18 months the corresponding figures are 0, 2.0, 2.2, 13.3, and 10.0.

The total mortality subsequent to discharge was much less in the females than in the males—14 deaths of 338 women and 25 deaths of 292 males. Both sets when subdivided as in Table II lead to very small groups at risk, and the smaller number of deaths in the females is likely to give rise to more erratic results. Further data are required to show how closely the prognosis in females is related to B.S.R. at discharge, but it may at least be concluded from the present figures that it is distinctly associated in males and is associated to some extent in females.

The B.S.R. was estimated, it will be recalled, at admission as well as at discharge. These figures enable the *changes* in B.S.R. during treatment to be related to history after leaving the sanatorium (noting again that deaths *during* treatment are not included). These changes are set out in broad groups in Table III, and it was found that all the 25 deaths of males occurred among the 116 patients with a B.S.R. of 10 or over on admission and still retaining that level on discharge; there were therefore no deaths among the 68 males who were admitted with a B.S.R. of 10 or over which during treatment fell below that level, and none in the small group of 13 males whose admission rate was under 10 but at discharge had risen above 10. Of the 14 deaths of females, 12 occurred, similarly, among the 177 patients who had a B.S.R. of 10 or over at admission and showed no fall below 10 during treatment. The remaining 2 occurred in the 46 patients who had a B.S.R. of 10 or over at admission but had improved to 5–9 at discharge. There were no deaths, it may be noted, in the 28 females whose B.S.R. at entry was under 10 and at discharge had risen to over 10.

TABLE III

	Males	Females
(*a*) Stationary B.S.R.		
0–4 at admission and discharge	35	15
5–9 " " "	24	38
10 or over " " "	116	177

5–9 at admission, 0–4 at discharge	30	15
10 or over " 5–9 "	40	46
10 " " 0–4 "	28	12
(*c*) Deterioration in B.S.R.:		
0–4 at admission, 5–9 at discharge	6	7
0–4 " 10 or over "	2	3
5–9 " 10 " "	11	25

---

* The numbers exposed to risk were obtained from the formula:

$$E_{(x)+t} = E_{(x)+t-1} - d_{(x)+t-1} - \tfrac{1}{2}[W_{(x)+t-1} + W_{(x)+t}] - e_{(x)+t}$$

Where t = number of 6-monthly periods after discharge ($t_0 = 0-6$ months).

$E_{(x)+t}$ = number exposed to risk of dying in period t.

$d_{(x)+t}$ = number of deaths in period t.

$W_{(x)+t}$ = number lost sight of in period t.

$e_{(x)+t}$ = number passing out of the experience at the end of April, 1940, having survived for t complete periods.

The B.S.R. group of 10 and over covers a variation from 10 to 100, and in Table IV a further subdivision is made of these values, taking 35 as an arbitrary dividing-line. The numbers at risk are so small that the trend of the death rates can be accepted as only suggestive; but the indication they give is that later mortality is likely to be lower with B.S.R. remaining steady at 10–35 or improving during treatment to that level from over 35 than it will be with an unimproved level of 35 or over at admission and discharge or a rise from 10–35 to over 35.

Table IV.—*Percentage Mortality Rates after Discharge in Relation to High B.S.R. Figures*

18–24 .. .	2·8	—	—	—
Total deaths ..	6	3	1	2
„ patients	112	25	22	18

The conclusions from these statistics are therefore: (1) The higher the sedimentation rate on discharge from the sanatorium the more unfavourable has the average prognosis been. The association is clear with males, less clear but highly probable with females. (2) The bulk of the mortality experienced fell on the patients who were admitted with relatively high sedimentation rates and retained them at discharge. There is not sufficient material to determine whether the prognosis was better in those whose B.S.R. fell during sanatorium treatment than in those whose B.S.R. rose or failed to improve, but there is a suggestion that this is likely to be the case.

We wish to express our thanks to Dr. A. Bradford-Hill and Dr. R. C. Wingfield for their help and advice in the preparation of this article.

NON-PENETRATING INJURIES OF THE ABDOMEN

BY

TH. SCHRIRE, M.A., M.B., F.R.C.S.
Surgical Registrar, Groote Schuur Hospital, Capetown

In these days of motor, industrial, and war accidents many of us frequently have to give an opinion on patients suffering from non-penetrating injuries to the abdomen. These injuries, as often as not, are sustained under unknown conditions, and the patient's history is of necessity vague and unhelpful. It is therefore timely to consider and evaluate the points that should influence the surgeon in answering the question, "Should this abdomen be opened or not?"

The answer to this question cannot be found in a single symptom or sign. It is a notoriously difficult problem, and Massie (1923) states: "There is no escaping the conclusion that early diagnosis is almost impossible. The surgeon must be guided more by a general consideration of the clinical picture than by the presence or absence of any particular sign." While no clinical diagnosis is infallible, guided by the following points one has been able to give a definite and immediate answer in most of the doubtful cases presented by a succession of harassed house-surgeons.

Diagnostic Points

Shock.—If seen soon after the accident the patient is in a state of typical and profound shock. Even apart from the fact that operation is out of the question in such a condition, the shocked patient is no fit subject for a thorough examination. The treatment of shock takes precedence over everything except external haemorrhage, and all agree that this latter should be temporarily controlled by the simplest means. If internal haemorrhage is of such magnitude as to prevent the patient recovering from the primary shock without operation, it can be safely assumed that a desperate operation to control the bleeding will kill him even sooner. One must be prepared to face the fact that a patient who is so severely injured that he bleeds to death internally without recovering from his primary shock is not a subject for surgery at all. But in most cases there comes a time when, under adequate treatment, the primary shock passes off and internal haemorrhage ceases spontaneously but temporarily. This time is usually about two hours after resuscitation measures have been started, and its recognition is the hall-mark of a good surgeon. To operate too soon will intensify the shock, and to operate too late will allow the blood pressure to recover and bleeding to restart; later, secondary shock sets in. Blood transfusions will help to increase the margin of safety, but as a rule the optimum time is short, and its recognition is a matter of urgency. Experience alone will help here, and it is in these doubtful cases that the experienced surgeon will operate on a larger proportion of patients, and though his percentage of operative failures may be greater he will show a larger absolute number of successes.

Pain.—This is always present, its severity being of very little importance. The pain is often localized to the part struck, and very often bruising and superficial abrasions will help to indicate the spot. While this is the site of maximum damage, it does not follow that a viscus has been injured: some of the most painful injuries are unaccompanied by any visceral damage at all. Often the pain may be referred and may be due to broken ribs, with injury to the lower six intercostal nerves, or to intrathoracic visceral damage. Occasionally the pain is referred to the tip of the right or left shoulder. This does not necessarily mean that there is subdiaphragmatic irritation; it may be due to trauma to the diaphragm itself or to supradiaphragmatic pathology. Still another pitfall is the presence of an unsuspected lesion of the spinal cord. There may be the most excruciating abdominal pain from such a lesion, which is not necessarily thoracic. I have had the mortification of performing a negative laparotomy on a patient who recovered and was later shown to have a fracture of a cervical vertebra with no other neurological signs to help in the diagnosis.

Tenderness.—All injuries of the abdomen will show some degree of tenderness. This tenderness may be acute, though the damage is superficial: an injured viscus usually shows local tenderness, but if this sign can be elicited at a neutral part of the abdomen it can be safely assumed that there has been some spilling of visceral contents. Because of this spill into the general peritoneal cavity *remote* tenderness can always be elicited, and is a valuable diagnostic point.

Rigidity.—For the same reasons *local* rigidity may be ignored. Its presence within the first hour or so cannot be elicited with assurance. Later, local bruising of the belly wall will give a wrong impression of rigidity. *Remote* rigidity is of vital importance and is diagnostic of perforation; it demands immediate laparotomy if the general condition of the patient will allow it. Its presence implies irritation of the parietal peritoneum, which can only be due to free blood or visceral contents in this cavity.

Pulse Rate.—All cases suspected of internal injuries are put on to half-hourly pulse charts as a matter of routine. A rising pulse rate which cannot be accounted for by external haemorrhage or by intrathoracic injuries should call urgent attention to the abdomen. A rising pulse rate alone is not an indication for laparotomy but for a careful general examination. In injured children the pulse rate often rises to 130 or 140 for no demonstrable reason, and, though it requires considerable restraint to hold one's hand, an hour or so may be safely spent in watchful anticipation. As characteristic of peritonitis this sign comes on late, and every effort should be made to diagnose without its aid.

Liver Dullness.—Loss of liver dullness often implies that free gas has become interposed between the liver and the parietes. It also is a late sign and should not be awaited. If the abdomen is distended this sign is not significant, but in the absence of distension or when combined with other signs it becomes important.

Leucocytosis.—The most bizarre counts may be found. Some cases with counts up to 30,000 white cells per c.mm. have shown no perforation and have cleared up on conservative expectant treatment, while others with equally large counts have required suture of ruptured viscera. Similar experiences can be recalled in the presence of normal and low blood counts. This investigation is often not available, and is usually not helpful.

Radiography.—When the primary shock has passed off it is the easiest thing to sit the patient up in bed and, after slipping a loaded casette behind his back, to take a radiograph of the upper abdomen in the erect position. Pneumoperitoneum as indicated by fluid levels under either or both domes of the diaphragm is pathognomonic of free gas in the abdomen and is a simple, safe, and positive indication for laparotomy. The finding is of great positive value, but if negative it does not rule out haemoperitoneum, a ruptured bladder, or a small tear in the alimentary canal.

And, finally, if there is still doubt after one examination, re-examination an hour later has been found to be of the greatest value. Progressive tenderness or progressive rigidity is especially looked for, and a reassessment of the whole condition can then be made without the loss of too much valuable time. A comparison with the earlier examination will usually lead to a certain diagnosis.

Summary

The classical signs of ruptured viscera are considered.

The finding of tenderness and, more important, of rigidity at any part of the abdomen remote from the site of primary injury is considered to be the surest indication for laparotomy.

X-ray findings, if positive, can clinch the diagnosis.

The value of re-examination one hour later in doubtful cases is stressed.

REFERENCE

Massie, G. (1923). *Lancet*, 2, 643.

At the annual general meeting of the Society for Relief of Widows and Orphans of Medical Men, with Mr. V. Warren Low in the chair, the report and accounts for 1941 were presented and adopted. Sixty-three widows and two orphans received grants during the year, and £4,371 was distributed among them, each widow over 65 years of age receiving £75 and those under 65 £60, and each orphan received at the rate of £50 per annum. Relief is granted only to the widows or orphans of deceased members. Membership of the society is open to any medical man who at the time of his election is residing within a 20-mile radius of Charing Cross. Election is by ballot. The invested funds of the society amount to £139,000. Capital may never be sold and used as income. Full particulars may be obtained from the secretary, at the offices, 11, Chandos Street, Cavendish Square, W.1. Since the foundation of the society, in 1788, there have been six secretaries only. The first held office for 27 years and the fifth for 37 years; the sixth, Mr. Edward J. Blackett, has so far held office for 37 years.

Medical Memoranda

Chronic Headache caused by "Silent" Sinusitis

Usually we take very little notice of a headache. It may be due to a cold, influenza, or some other upset, and we know that when the cause disappears so will the headache. When no cause can be found, and yet the headache persists, constant or intermittent, severe or mild, month after month, year after year, then it becomes an unmitigated nuisance and a hindrance to life. Remedies and suggested causes fill the pages of our textbooks, and advertisements of quack remedies abound—sure signs that none can be relied on. Two cases of this nature are reported to show how easily the actual cause of the headache may be missed and the patient thus condemned to long years of helpless misery.

Case 1.—A spinster aged 59 had suffered from constant severe headache for 7 years. At times she had taken as much as 90 grains of aspirin in a day. Since there seemed to be no hope of relief her friends began to fear suicide. Sinusitis had been suspected, and she had been examined by three rhinologists, who were all agreed that there were no clinical signs. The first supported his opinion by radiographs; the second, after washing out the nasal cavities and examining the secretion microscopically, was emphatic that there was no infection. Nevertheless, the fact that the patient had post-nasal catarrh, together with marked contraction of her fields of vision, convinced me that there *was* sinusitis, and when at my request the third rhinologist opened the left antrum the disease was seen. A week after the antrostomy there was a sudden profuse flow of blood and mucus from the left nostril, and the pain at the vertex ceased. A year later she wrote: "I have practically given up aspirin, my head is so much better."

Case 2.—An unmarried woman aged 39, first seen in 1930, had had severe headaches from childhood. They were often quite incapacitating, and latterly had occurred daily. In the hope of relief all her teeth had been removed, her tonsils enucleated, and her septum straightened. When these measures failed no further suggestion could be made by rhinologist, ophthalmologist, or neurologist, and the patient and her doctor were in despair. Clinical signs of sinusitis were entirely absent even during the septum operation, and the *x*-ray report was negative. There had never been any catarrh. Nevertheless, the extreme contraction of her fields of vision led me to diagnose sinusitis as a cause of her headaches. Conservative treatment by nasal medication resulted in considerable nasal discharge and prompt relief of the headache. A year later she had "the best holiday of her life" and could "eat anything and go anywhere" without provoking the headache which formerly followed any indiscretion. In 1941, eleven years later, the patient reported again, well and happy, with only occasional moderate headache. (A fuller account of this case is given in *Proc. roy. Soc. Med.*, 1931, **24**, 891, in which the fields before and after nasal drainage are reproduced.)

These two cases are merely outstanding examples of scores of others in which the existence of sinusitis has remained unsuspected as the cause of headache for many years, sometimes for a lifetime. The hidden nature of the cause suggests an explanation for the frequency of cases of unrelieved headache and of "migraine." When it is realized that though there may be nothing to be seen in the nose or in radiographs of the sinuses we can detect the activities of the hidden oedema around the inflamed sinuses by the fields of vision, these sufferers, hopelessly imprisoned by their own hidden sepsis, can be set free.

London, W. ROSA FORD, M.B.

Sudden Death from Lipoid Pneumonia

The following case seems worthy of record not only because it presents some unusual features in a comparatively rare condition but also because it points a moral.

CASE HISTORY

A patient of mine, a gardener aged 70, died suddenly, and I was instructed by the coroner to make a post-mortem examination. Twenty years previously the man had had a carcinoma of the left side of the tongue, removed by Mr. (now Rear-Admiral) G. Gordon-Taylor. After a preliminary gastrostomy an extensive operation was performed, which included removal of half the tongue, with part of the lower jaw, and a clearance of the lymphatic tissues in the left side of the neck. The gastrostomy was later closed, and he was able to carry on useful work as a gardener right up to the time of his death. On the morning of the day he died he went out to feed his fowls before breakfast, and as he did not return to his meal his wife sought him, and found him dead in the lavatory.

At the necropsy I could discover no evidence of any recurrence of the disease in his mouth or neck, and the old gastrostomy was soundly healed. On opening the thorax I found the mediastinum displaced over to the right side. There were dense pleural adhesions on both sides of the chest, and the right lung was almost completely collapsed. In the lower lobe of the left lung, and firmly adherent to the diaphragm below, was a hard mass, roughly pyramidal in shape, and extending up towards the hilum. It measured approximately 2 in. in each dimension. To the naked eye it resembled a neoplasm; but as I had some doubt as to its nature I sent a portion to a pathologist for section. The mediastinal lymph nodes were hard and fibrous, and the only other pathological findings were a few plaques of atheroma in the aorta.

Section of the tissue sent to the laboratory showed the case to be one of lipoid pneumonia, with very marked reticular fibrosis and numerous large vacuoles surrounded by giant cells. On further inquiry I found that the patient had indeed complained to his wife for some time of increasing dyspnoea on exertion, but had not consulted me about it, though I had been seeing him during the winter to issue certificates for milk and eggs. He had also been in the habit of taking liquid paraffin as a laxative.

COMMENTARY

Lipoid pneumonia was first described by G. F. Laughlin in 1925. Most of the early cases occurred in debilitated children whose powers of deglutition were impaired or whose cough reflex was ineffective. In later years a greater number of cases have been reported in adults, though they have been more often demonstrated at necropsy than diagnosed during life. A large proportion of these cases occurred in patients whose deglutition was affected either by carcinoma of the mouth or throat or by some nervous disease (Freiman *et al.*, 1940). Brown and Biskind (1941) have stressed the occasional resemblance between lipoid pneumonia and carcinoma of the lung, as in this case, though other cases may resemble a low-grade pneumonia (Propert, 1940). Unusual features of the case were the pleural adhesions and the collapsed right lung. Pleurisy is said to be a very rare complication.

The American Medical Association has already drawn attention to the dangers of oily nasal sprays, and I now feel that a warning should be given against the indiscriminate use of paraffin as a laxative by patients with affections of the mouth and throat.

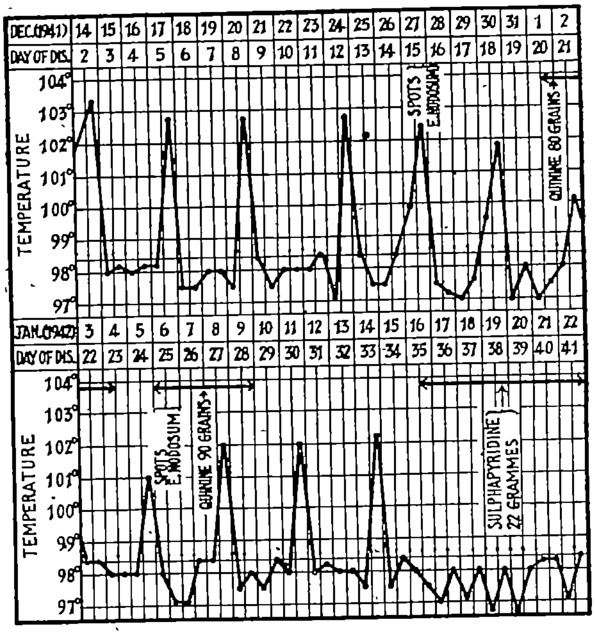
Meningococcal Septicaemia resembling Malaria

Meningococcal septicaemia usually presents a fever remarkable in its irregularity, variability, and duration, and seldom exhibits the regular periodicity shown in the accompanying temperature chart.

CASE REPORT

I saw the patient, a soldier aged 26 who had never served abroad, on Jan. 17, 1942. He had been quite well until Nov. 2, 1941, when he suddenly became ill with pains in the legs, arms, and shoulders, with high fever. The fever continued for a week, and he was treated at his regimental medical post. Afterwards he went on leave, during which he had occasional attacks of fever. Some 6 weeks later, on Dec. 13, he was admitted to hospital, where he continued to have periodic attacks of fever, each of which lasted 12 to 24 hours. Simultaneously with the attacks he had headache, rigor, and sweating, and complained of some pain over the splenic region, but was quite well in between the attacks. On Dec. 27 and Jan. 6 some scattered erythematous spots were seen on the abdomen, and also some tender spots resembling erythema nodosum appeared on the legs. Two attempts to recover meningococci from the blood proved unsuccessful, and blood films were examined for malarial parasites with negative results. Blood counts showed a leucocytosis up to 22,000 per c.mm., with a polymorphonuclear increase during the attacks, but in the interval the leucocytes fell to 8,200 per c.mm. The blood sedimentation rate was 48 mm.; urine and stools showed no abnormality; and the Kahn test was negative. The pulse rate rose during the attacks but never exceeded 104, and the respirations remained at about 20 a minute throughout.

On Jan. 1 a course of quinine bihydrochloride was started, but there was no effect on the recurrence or periodicity of the fever. On Jan. 16 sulphapyridine was given in doses of 2 g. four-hourly, and continued for one week in diminishing dosage, making a total of 22 g. The effect was dramatic, for the fever did not recur and the patient's convalescence was rapid and uninterrupted. No other cases of meningococcal infection were reported from this man's unit. The resemblance of the fever to quartan malaria is close, for it started first as a continuous form of fever and then settled down to a regular quartan periodicity (except for one period from Dec. 20 to 24), with rigor and sweats throughout.



Meningococcal septicaemia is far from uncommon, being one of the causes of a prolonged irregular fever that is apt to be overlooked, and there is much truth in the saying, "When you see erythema nodosum, think of meningococcal septicaemia."

This case shows that sulphapyridine is as specific for meningococcal septicaemia as quinine is for malaria or antimony for leishmaniasis.

I should like to express my thanks to Major-Gen. G. A. Blake, D.D.M.S., Western Command, for permission to submit this note for publication, and to Lieut.-Col. J. C. Hunt, R.A.M.C., for his kindness in giving me the clinical notes.

ROBERT PRIEST, C.B., M.D., F.R.C.P.,
Consulting Physician, Western Command.

The following medical promotions in and appointments to the Order of the Hospital of St. John of Jerusalem were announced in the *London Gazette* of June 23. As Knights: Col. Sir Richard Needham, C.I.E., D.S.O., M.D., F.R.C.S., Capt. R. J. Isaac, L.R.C.P.&S.Ed. As Commanders: Capt. H. F. Powell, M.B.E., M.D., Lieut.-General Alexander Hood, C.B., C.B.E., M.D., Lieut.-General W. H. Hamilton, C.B., C.I.E., C.B.E., D.S.O., F.R.C.S. As Officers: Dr. C. C. H. Binns, Lieut.-Col. C. H. James, C.I.E., F.R.C.S., Dr. A. M. Barford, Major G. F. P. Gibbons, O.B.E., M.B., Mr. J. R. M. Whigham, *M.C.*, F.R.C.S., Dr. W. P. Kennedy, Surg. Cmdr. J. A. Watson, L.M.S.S.A., Mr. H. R. Rishworth, O.B.E., F.R.C.S. As Serving Brothers: Dr. R. MacLeod, Capt. R. S. Harper, M.R.C.S., L.R.C.P., R.A.M.C., Dr. F. C. Mann, Dr. E. H. Shaw, Dr. W. F. Mason, Dr. M. W. Sellars, Capt. B. Singh, I.M.S., Dr. W. Fraser, Dr. R. Dick, Dr. W. Bain, Dr. S. K. Poole, Dr. P. B. Wood, Dr. E. P. Coyne, Dr. T. B. Gilchrist, Dr. J. Kirkwood, Dr. F. S. Hone, Capt. G. B. Thomas, F.R.C.S., I.M.S. As Associate Serving Brother: Said Abdul Rahim Dabbagh, M.D. Beirut.

Reviews

THE MARCH OF MEDICINE

The March of Medicine New York Academy of Medicine Lectures to the Laity, 1941. (Pp 154 $2 00 or 13s. 6d) New York: Columbia University Press: London: Oxford University Press. 1941

We are accustomed to look forward to the publication of the "Lectures to the Laity" delivered at the New York Academy of Medicine, nor does the sixth volume of that series disappoint that anticipation. Dr. Alan Greg leads off with "Humanism and Science," in which he emphasizes the great importance of realizing that illness makes a severe attack on the patient's whole personality. Only imaginative experience, he declares, can appreciate the assault on the image that the individual has formed of himself—" an arcanum, a secret inner chamber of his being, ineffably precious and delicate. . . . It is not his shortness of breath, it is his tumble from omnipotence which infuriates and exhausts": the domestic tyrant stricken with heart disease. "A miraculous moment comes when the doctor becomes the treatment." As humanism in the 15th century freed man from an extreme preoccupation with the exultations and threats of the theologians it may serve now to counterbalance those of the specialists in whatever department.

Dr. Sigerist reviews the career of Paracelsus in the light of the four hundred years that have elapsed since his death. With great literary charm and persuasiveness he presents his subject in a more favourable light than is usual. Doubtless Paracelsus threw aside the dead hand of Galen—so much to the good. What is more doubtful is the value of the astrological system he put in its place.

Dr. Healy discourses on psychiatry and the normal life, in which he reminds us that a normal man is simply a mental concept which is based on averages and is conditioned by the environments of time and place. His conclusion is that with our countless millions of unused brain cells we must have the potential ability to develop more of them for the good of human society. Indeed, if such potentialities are not realized he thinks our very survival is in doubt in the light of our increased powers of self-destruction.

Dr. Edman intervenes as a layman in a lighter vein than is usual with professional philosophers. He finds that his awe of physicians is not reciprocated by them as awe of philosophy, but points out that what an intelligent physician gives his patient is what a philosopher tries to give his readers. The doctor tries to make his patient grow up, to make him see himself and his situation without conflict or evasion. Maturity means facing the issues of existence without illusion, but this does not mean disillusion. Thus his lecture accords pleasantly with Dr. Alan Greg's.

Dr. Riddle takes an encouraging view of "The Promise of Endocrinology." It is interesting to see how the conception gains ground of an integration of that system under the leadership of the anterior pituitary, itself in turn largely controlled through the centres for emotional expression. He considers that in the future the hormones are more likely to be applied to control the emotions than the intellect, and regards the former as playing a larger part in personality than the latter. He lays down the principle that all men, except identical twins, are created genetically *un*equal.

Dr. F. C. Wood winds up an interesting series by a plain statement of "What we do know about Cancer," in which he aims at depriving it of the terrors of the unknown, a very important task. He points to records collected by the American College of Surgeons of 35,000 patients who have lived for five years or more after operation for cancer, statistics which could not have been obtained twenty years ago.

JUNG'S TEACHING

The Psychology of C. G. Jung. An Introduction, with Illustrations By Dr Jolan Jacobi. (Pp 169 12s.) London: Kegan Paul, Trench, Trubner and Co.

Every philosophical psychologist seeks to enunciate a formula that will explain human behaviour. One of the most complete of these is associated with the work of C. G. Jung. Human behaviour being what it is—of infinite variety—the more complete the formula the more complex does it become and the more difficult is the story it has to tell. There is consciousness and unconsciousness; but they are complementary and constantly interacting; so are the personal and the collective unconscious. Attitudes of extraversion and introversion are likewise complementary, and a man may therefore exhibit one in his life but the other in his work. The functions of thought and feeling, of intuition and sensation, are almost mutually exclusive, but each pair may interact with one dominant function and so increase complexity.

All this works dynamically in constant interaction, preserving a plastic balance between opposites; but the energy can be displaced or transformed so that "abnormal" behaviour results. Jung does not in any way refer theoretical "structure and function" of the psyche to the structure and function of the body; consequently in some ways his teaching is more a religion than a science, and is said to have a wider application than "medical healing." In practice he works not only analytically but also synthetically, having regard to aims as well as to causes. The link between the conscious and the compensatory unconscious is the symbol, especially as met with in the dream and in fantasy. The aim of psychotherapy and analysis is to bring the unconscious material into consciousness so that the two may interact harmoniously. This harmonious interaction can never be absolute, only relative; so "cure" can never be complete, or, in other words, man can never be perfect and must always have some neurotic trend.

One of the most important opposites is the image ("anima" or "animus," as the case may be) of the other sex in the unconscious. The first of these images is always the parent of the opposite sex, and the freeing of the child's consciousness of the unharmonious intrusion of this image is one of the most important psychological processes in life. Behind this lies a more fundamental image, called by Jung the "magna mater," materialism in the woman and spirituality in the man. When all these opposites are integrated, then the whole man, the true self, may emerge and the goal of the analysis and synthesis be reached. The symbol of this emergence appears in all sorts of cultures, especially oriental, and this fact seems to point to its universal validity.

The story of Jung's teaching is well told in this little book, but it is not easy reading, and it is doubtful whether those not already acquainted with his work will obtain a great deal of enlightenment from it.

TREATMENT OF SYPHILIS

The Modern Treatment of Syphilis. By Joseph Earle Moore, M D; with the collaboration of Jarold E Kemp, M.D, Harry Eagle, M D, Paul Padget, M D, and Mary Stewart Goodwin, M.D. Second edition (Pp. 674; illustrated 38s 6d) London: Baillière, Tindall and Cox.

Nearly nine years have elapsed since the first edition of this work appeared; a second edition is therefore due, more particularly since the incidence of syphilis not only has ceased to fall but is definitely rising, in this country at any rate. No epoch-making discoveries have occurred in the interval, but our knowledge has advanced in many directions and improvement in serological technique has been noteworthy, but, alas! much more so in the United States of America than in Great Britain.

The increased responsibility thrown on the four collaborators, Drs. Kemp, Eagle, Padget, and Goodwin, has added much to the authority of the book. Perhaps its most striking new feature is that dealing with mapharsen, a preparation which has found much favour in the U.S.A., but which so far has attained little popularity in this country. Dr. Moore is evidently much impressed with its efficacy, since he inclines to its use in preference to neoarsphenamine in early syphilis. Whether time and experience will bear out his contention seems at least doubtful; in dealing with such a disease as syphilis the wise man prefers to wait many years before he commits himself to a eulogy of a new drug. On the other hand massive-dose arsenotherapy, which has been so much boomed by certain workers, is not recommended in the present state of our knowledge. Much is made of the quantitative Wassermann test, but the critical serologist will inquire whether the progressive reduction in the amount of human serum employed should not be taken into account; presumably the serial dilutions are made with physiological saline. The quantitative test is very valuable in estimating progress in the so-called reagin-fast case, and it seems a pity that more use is not made of the sigma (Dreyer-Ward) reaction for this purpose.

This excellent book is essentially one for the specialist. That the treatment of syphilis should occupy more than 600 pages indicates that the subject, late syphilis at any rate, is not one for the general practitioner or the inexperienced.

HANDLING OF GAS CASUALTIES

Gas Cleansing Stations A Manual of Procedure during Gas Attack for Casualty Service Personnel, Members of the Home Guard, Industrial Undertakings, and the Public By Leslie Stewart, Training Officer, First-aid Posts, City of Manchester. (Pp. 64. 2s. 2d. post free) London: Jordan and Sons, Ltd.

As explained in the introduction, the purpose of this handbook is to assist members of the casualty services to obtain an understanding of the treatment of gas-contaminated casualties. The subject is dealt with in 8 short chapters and an appendix, comprising in all 63 pages. The writing is simple and direct and the approach practical. The book should have a wide usefulness in the casualty services throughout the country. Official instructions on the subject of preparedness for gas attack have undergone many changes during the last 5 or 6 years, the chief being that, whereas attention was first specially directed to measures against non-persistent gas, emphasis is to-day placed upon the dangers of blister gas. This excellent handbook deals with the latter problem. We have, fortunately, had no experience of gas attack and we hope that gas will not be used. Should it be used, mental preparedness on the part of all Civil Defence personnel will lessen the risks of panic and facilitate the treatment of casualties.

For the purpose of instruction the author has postulated a simple situation in which blister-gas casualties require treatment. It would be wise when placing this book in the hands of volunteers to remind them that the first gas attack may be with non-persistent gas or with a mixture of non-persistent and blister gases. Very different practical problems will arise according to the type used. For example, a few drops of blister gas inside a gas mask will quickly make the wearer a severe casualty; the air lock in its application to blister gas is for the purpose of affording protection against heavy concentrations of vapour given off from collections of discarded contaminated clothing. If and when the attack comes we shall learn much about our anti-gas organization, and shall improvise and improve and go on doing so until victory is won. In the meantime all those responsible for or preparing to assist in the treatment of casualties will find this careful and practical little book of great assistance.

Notes on Books

Unlike some authors, Mr. **HAMILTON BAILEY** apparently reads the reviews of his books and profits by them. This is flattering to the reviewer and advantageous to a new edition. The inclusion of certain signs—e.g., Kocher's test and Berry's sign—in the eighth edition of *Demonstrations of Physical Signs in Clinical Surgery*, the omission of which we mentioned in our notice of the last, is naturally an improvement, and we have little but praise for this excellent work. Prof. Wood Jones, referred to on p. 133, might be given a footnote as are other authors, and diffuse neurofibromatosis, p. 25, might be called, as is customary, after von Recklinghausen. Mr. Sampson Handley, p. 227, should be described as consulting surgeon to the Middlesex Hospital. The winged scapula (B, Fig. 437, p. 299) would be better shown if photographed from the other side, and "ulnar paradox" might be mentioned in connexion with lesions of the ulnar nerve. We were under the impression that circumflex, not axillary, p. 317, was the old terminology for this nerve. These, however, are minor features to criticize in an edition which is a great credit to both author and publisher. This is now a standard work which should be read and remembered by every medical student. It is published at Bristol by John Wright and Sons, price 25s.

It is difficult to understand for whom the little book, *Visual Outline of Psychiatry*, is really intended. Admiration for Dr. **LELAND HINSIE**'s ingenuity in compressing so much into so little space must be expressed by anyone well acquainted with Freudian theory and practice. Even so the section on the organization of the mind is better than that on the psychiatric syndromes, and the substance of the book can only be of use in reminding and not in instructing the reader. For the student, however, at least in this country, the book is surely useless if not dangerous. It is inconceivable that he could pass an examination on purely Freudian teaching, and few examiners would be pleased if he were to dismiss all the work on convulsive therapy in schizophrenia in one line while advocating deep analysis as a cure, for most consider that this has been singularly ineffective in the true psychosis. Nor would the student be popular if he were to trot out such expressions as "altrigenderism," "heterogenitality," or even "schizoidism," in every paragraph of his examination paper. The book is published in this country at 12s. 6d. by the Oxford University Press.

Two members of the Department of Bacteriology of the University of Wisconsin Medical School, **PAUL F. CLARK** and **ALICE SCHIEDT CLARK**, had the happy idea of compiling a calendar of biology and medicine, and the University of Wisconsin Press have published it at Madison under the title *Memorable Days in Medicine* ($2). The months of the year form the chapters of this pleasant bedside book; and each day has one or more entries for the birth or death of a man or woman, or the foundation of an institution, famous in the annals of our profession or of the biological sciences, or the launching of some enterprise. In a short foreword the authors disarm the critic of their fragmentary material: "We apologize for omitting your favourites; we have omitted many of our own." The print is good, there is a satisfactory index, and some portraits are reproduced, including an unfamiliar photograph of Charles Darwin without his beard and moustache. When the text is revised for a new edition a few minor slips should be corrected—e.g., "Sir" Stephen Paget, "Sir" Richard Bright, and the misspelling of Sir Humphry Davy's first name. We wish we could challenge the distressing statement that no obituary of Thomas Addison appeared in either the *Lancet* or the *British Medical Journal*.

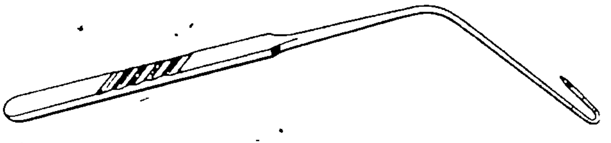
We have previously commended *Approved Laboratory Technic*, by **J. A. KOLMER** and **F. BOERNER**, as a comprehensive bench book dealing with clinical pathology in all its aspects. The third edition has been embellished with an appendix describing fourteen new methods, including those for the estimation of prothrombin, vitamin C, and various sulphonamide compounds, but the original text, which is the work of twenty-eight authors, is little changed. The chapter on agglutination tests, one of several the authorship of which is undisclosed, needs revision, and we would again suggest that the long lists of bacteria liable to be found in various types of material are misleading rather than helpful: no fewer than twenty-one, including *B. subtilis*, "*B. Zur-Nedden*," and "*B. anthracsis*," are said to occur in the eye. The greater part of the book is a prolific source of useful technical information, and the illustrations are excellent. It is published at 42s. by D. Appleton-Century Company.

Preparations and Appliances

NEEDLE FOR REPAIRING FEMORAL HERNIA

Mr. **JOHN W. STRETTON**, F.R.C.S., Kidderminster, writes:

The accompanying sketch, reproduced half-size, shows a needle made to my order by Messrs. Allen and Hanburys. It is the latest pattern of a needle I have been using for years. It is designed to pass sutures through the ligament of Astley Cooper when repairing a femoral hernia.



The needle is threaded (it will take No. 2 silk); its point is first passed, not through, but beyond this ligament, and then passed through the ligament from the far side. Now the needle point is advanced towards the surface, and then retarded slightly to prevent the silk lying too tightly against the needle. Non-toothed dissecting forceps bring the suture to the surface. The bent handle gives a clearer view.

I am indebted to the makers for their help.

Treatment of Scabies.—Burroughs Wellcome & Co., 12, Red Lion Square, W.C.1, advise us that dimethylthianthrene (mesulphen *B.P.C.*), referred to in the *Journal* (July 4, p. 3), has been issued commercially by them since October, 1940, under the brand name "sudermo." Supplies, though limited, are still available.

THE EVILS OF LONG WORKING HOURS

Now that the war will soon be entering on its fourth year, with no prospect of an early termination, it is more than ever important that we should pay careful attention to the question of the hours of labour of our industrial workers. If the hours are such as to induce ill-health, it is obvious that the longer they are continued the more they are likely to do permanent harm to the health of the nation. The evils of excessive hours have been pointed out over and over again by almost everyone who has taken the trouble to investigate the subject. The Select Committee on National Expenditure, in their seventeenth report, said that "they regret to report that the lessons which the last war should have taught seem largely to have been ignored," while the Chief Inspector of Factories, in his last annual report, was similarly of the opinion that "some valuable lessons of the last war had been widely forgotten or were not yet sufficiently appreciated," and he added, "I have particularly in mind the lessons that excessive hours mean less production." A return from 5,493 factories showed that in nearly half of them the women were working between 57 and 60 hours a week, and the disadvantage of long hours was well illustrated by the experience of a deputy chief inspector of factories, who found that at a factory which had been working 54 hours it was impossible to maintain production until in every third week the hours were reduced to 48.

The Government, so far from doing anything to check excessive hours, seems inclined to extend them, at least in respect of those members of our industrial population who are least able to bear them. The Minister of Labour is taking measures to standardize a 52-hour working week in industry and 46 hours for clerical workers, and these hours are to apply to everyone, including juveniles aged 14 and upwards. The hours are not to be imposed by Order, but by a direction to the man-power boards, and there can be little doubt that they will frequently be taken advantage of. It will be remembered that under the Factories Act, 1937, juveniles of 14 and 15 are allowed to work only 44 hours a week without any allowance for overtime, so they are now to be permitted an extra 8 hours a week. This may not, at first sight, appear very excessive in wartime, but in fact it means that, instead of the usual 8-hour day, the juveniles have to work for 9½ hours, except on Saturdays. When the juveniles reach the age of 16 they are permitted, under the Factories Act, to work for 48 hours *plus* 6 hours a week of overtime—i.e., for 54 hours a week in all (for a limited period)—and when they are 18 the women are allowed to work for 54 hours with less limitation, while the men are not restricted at all. In the recent Parliamentary debate on factory welfare (July 22) Mr. Bevin said that they had had to do things about hours of labour which had been extremely distasteful, but that he was considering tightening up at an early date. During the course of the debate one member adduced instances where women were in factories for 12-hour periods. Another member gave details of young people under 17 working over 60 hours a week, while a third member stated that the war effort was definitely being hindered by the long hours now required from the workers.

Long hours of work almost inevitably put a greater strain on the women than on the men, not only because of their poorer physique and stamina, but because of the time they have to devote to housework and to shopping. The shopping is much more of a trial than in peacetime for several reasons. For instance, in an industrial centre such as Birmingham a number of the shops close at five o'clock, which makes it impossible for the women employed on a normal working day to do any shopping. In a London area it appeared that one-third of the women shopped on Friday nights and two-thirds on Saturday afternoons, and they usually had to queue. As they could not get to the shops in the mornings they found it practically impossible to get cooked meats or any of the non-rationed foods. An additional strain, which is much greater in wartime than in peacetime, is brought about by transport difficulties. Many of the workers spend well over an hour each morning and evening in getting to and fro between home and factory, and this adds considerably to their fatigue.

Evidence showing that war workers are suffering from over-fatigue comes from many sources. In the *Times Educational Supplement* (June 27, 1942) there is an article on "Youth in Industry" and a report from the Lincoln Youth Committee, which relates more especially to the 16–17 age group. The maximum hours of work allowed in wartime, says Lincoln, "seem beyond the physical capacity of juveniles. Many of the boys admitted a permanent feeling of fatigue," while a Yorkshire borough finds that many boys seem to be "mentally and physically exhausted." Stirlingshire refers to young people as "physically and mentally overwrought," while Birmingham reports on the strain of long hours of work and compulsory fire-watching. Again, when the Ministry of Health estimates were debated in Parliament a month ago, a number of members voiced the serious effects of long hours of work on young people, and Mr. Kenneth Lindsay reminded the House that it is nobody's business to look after the health of the young people between 14 and 18. Statistical evidence relating to the effects of wartime conditions on the health of the nation has been recently adduced in this *Journal*, and some of it is very disquieting. Dr. Percy Stocks,[1] when comparing the tuberculosis mortality in 1939–41 with that observed in 1937–9, showed that there was an excess of 11% in young women aged 15 to 19, and of 21% in those aged 20 to 24. The corresponding figures for the death rates in 1914–16 were 22 and 14% respectively, or nearly the same, on an average. In the latter half of the war, however, the tuberculosis rate rose very rapidly, till in 1918 it was 50% higher in the two age groups mentioned than in 1911–14. By 1920 the rate had fallen back almost to normal, and there can be no doubt that the wartime rise was due to excessive hours of work, coupled with overcrowding and malnutrition. It was especially marked in the large industrial towns, and the same condition appears to be holding during the present war. Drs. Laidlaw and Macfarlane[2] investigated 1,600 cases of pulmonary tuberculosis notified in Glasgow in 1941, and at the same time they inquired into the occupation and hours of work of the sufferers. They found that, as compared with 1938–9, women between the ages of 15 and 24 showed an increase of 33%, while their deaths showed an increase of 34%. The authors laid special stress on the effects of long working hours, for they found that members of the commercial and professional classes, who were for the most part working 48 hours or less a week, showed but little increase in tuberculosis as contrasted with the overworked industrial classes. Nearly a third of all the industrial women worked over 56 hours a week, and a few of them 65 hours or more.

---

[1] *British Medical Journal*, June 27, 1942, p. 789.
[2] Ibid., July 18, 1942, p. 63.

It may be maintained that even if long hours of work do induce ill-health in some degree, the need for achieving a maximum war production renders such hours unavoidable. The fallacy of this argument has been pointed out over and over again. Hours of work which are so long as to induce a state of chronic fatigue and ill-health, so far from increasing production, cause an actual deterioration. It is certainly the duty of all to work their hardest, and most people are capable of putting in rather more hours of work than they do in peacetime, but the margin is not great, and probably in most young persons of 14 to 17 it is non-existent. That is to say, the 44-hour week which juveniles of 14 and 15 are allowed under the Factories Act represents their optimum hours, while the 48-hour week, coupled with 6 hours a week of overtime, is in excess of the capabilities of young women of 16 and 17 if it is continued uninterruptedly for more than a very few months at a time. Young men, owing to their stronger physique, can easily cope with these hours, and it is remarkable how little adult men are affected by the very long hours often imposed on them. This does not prove that such hours are the best for maximum production. The men get into the habit of working at a slower rate, so it follows that they are paid higher wages for an output which they would achieve equally well if their hours were kept at a more reasonable level, such as 60 a week.

ANTIHORMONES

Animals which have had repeated injections of extracts of endocrine gland from a different species become refractory to the physiological action of these extracts. Collip and Anderson[1] were the first to demonstrate that this refractory state depends on the presence in the serum of the treated animals of a substance capable of neutralizing the specific action of the extract. They called the neutralizing substance an "antihormone." Since the experiments of Collip and Anderson, in which relatively crude thyrotropic fractions of the pituitary gland were used, "antihormones" to almost every fraction of the pituitary have been demonstrated. In spite of the tremendous amount of work which has been done in this field there is still no conclusive evidence as to the nature of the antihormones. Collip believed them to be antagonistic hormones, while the majority of other observers think they are true antibodies.

An antibody is usually defined as a substance which is produced in the animal body as the result of a stimulus given by an antigen administered parenterally, and which will react in some demonstrable way with the antigen which has stimulated its formation. Many attempts have therefore been made to show precipitation or complement fixation between hormone extracts and the antihormones they have evoked. Unfortunately many of the preparations used in these experiments have been relatively crude extracts of the pituitary or other endocrine glands. Such crude extracts contain, besides the hormone, a variety of antigens—for instance, serum proteins—which are characteristic for the species rather than the hormone. It is therefore not surprising that in the majority of cases the serum from any animal immunized against such an extract reacts as well in the test-tube with the serum proteins as with the hormone extract used in its preparation. When the most highly purified extracts so far available have been used for immunization, precipitating or complement-fixing antibodies have been formed in much smaller amounts or not at all. Even these small amounts of precipitin can, in most cases, be shown to be directed against species-specific antigens rather than the hormone itself. It has, furthermore, repeatedly been shown that the amount of precipitin present in the serum of an animal immunized against a hormone extract need bear no relation to the power of that serum to inhibit the physiological action of the hormone. This negative evidence cannot, however, be regarded as proof that antihormones are not antibodies. It may be that the hormone acts as a simple haptene capable of combining with its antibody but incapable of forming a precipitate, or the hormone may, as Zondek and Sulman[2] suggest, combine with its antibody in a manner not yet familiar to immunologists. If the hormone is a haptene it may exist in the animal body in combination with a carrier antigen which may be a normal constituent of other tissues or the blood of the same animal species. An antiserum to such a compound would then react not only with the hormone extract used for its preparation but also with any tissue extract containing the carrier only. Such an explanation is suggested by the recent work of Singer,[3] in which it was shown that antigonadotropin could be absorbed from a serum by an extract of kidney prepared in the same manner as that used in the preparation of the immunizing gonadotropic extract. Singer's conclusions are unfortunately based on experiments with small groups of animals and require confirmation. That a naturally occurring hormone (thyroxine) can behave as a haptene in artificially conjugated antigens has been strikingly demonstrated by Clutton, Harington, and Yuill.[4] The antibody evoked by such an artificial antigen has been found, moreover, to be capable of inhibiting the physiological action of injected thyroxine in test animals.

Studies on the physical and chemical properties and site of formation of antihormones have brought forward a great deal of evidence in favour of regarding them as true antibodies. Thus they are precipitated in the globulin fraction of serum, and show the same degree of resistance to heat and changes in H-ion concentrations as true antibodies. They depend for their formation on an intact reticulo-endothelial system irrespective of the state of activity of the endocrine glands. Furthermore, antihormones, like other antibodies, are formed, in any particular species of animal, only in response to material from a different species, and if only short courses of immunizing injections are given there is definite species-specificity of the antibodies produced. Species-specificity, as is well known, may disappear when long courses of immunizing injections are given. A pregnant woman, for instance, does not produce antihormones directed against gonadotropin, although during pregnancy gonadotropin is present in the body and is excreted in the urine in much greater quantities than normal. On the other hand, the human subject who receives, for therapeutic purposes, many injections of gonadotropic extract of bovine pituitaries ultimately becomes refractory, and the subject's serum is then found to contain antihormone capable of inhibiting the gonadotropin of bovine origin.

The investigations on the biological and immunological properties of the relatively crude extracts from endocrine glands as yet available, and the antihormones they evoke, have shown, therefore, that in many ways antihormones resemble true antibodies, and no undeniable evidence against this hypothesis has been cited. Nevertheless, final proof of the antibody nature of antihormones will depend on the demonstration of an *in vitro* reaction with the corresponding hormone in the test-tube. This demonstration will require hormone preparations which are immunologically as well as chemically pure. It seems more than likely that the way towards this final proof is through the field of synthetic immunochemistry.

SULPHONAMIDES AND THE METABOLISM OF BACTERIA

The importance of the sulphonamides as chemotherapeutic agents has been a great stimulus to research into their mode of action. During the last two years it has been shown that *p*-aminobenzoic acid will inhibit the bacteriostatic action of the sulphonamides on a wide range of organisms, and is even necessary for the growth of more nutritionally exacting bacteria. The similarity in structure between *p*-aminobenzoic acid and the sulphonamides, and a study of the concentration of the drugs necessary for inhibition, have led to the notion that sulphonamides act by competing with *p*-aminobenzoic acid for enzymes whose proper function is essential to growth. Wood[1] has extended previous observations by finding that the bacteriostatic potency of each of six sulphonamides is directly proportional to its ability to counteract the antibacteriostatic action of *p*-aminobenzoic acid. So, although there may be a very large disproportion in the concentration of the competing substances, the linear relationship between them is nevertheless interpreted as indicating competitive inhibition. The circumstantial evidence for this theory is very great, but its final proof must await the identification of the enzyme system involved. Macleod,[2] investigating the distribution of inhibitors of the sulphonamides among animal and bacterial extracts, found, however, that some were still active when the *p*-aminobenzoic acid had been removed by extraction with acid ether. And Green and Bielschowsky[3] have encountered similar extracts in which the inhibition seemed to be specific, as most of the growth-promoting factors had already been destroyed. Kohn and Harris[4] have now produced direct evidence that methionine, a naturally occurring amino-acid containing sulphur, has the property of inhibiting the bacteriostatic action of sulphonamides on *E. coli*. There may be other such inhibitors of unknown constitution in proteose-peptone. The inhibition of sulphonamides by methionine must be different from the inhibition by *p*-aminobenzoic acid, for there is no close structural resemblance to the sulphonamides, and the inhibition is seen only in a relatively poor salt-glucose medium and with low concentrations of sulphonamide. On the other hand the specificity of the inhibitor is great; no similar substance will produce the inhibition, and the *l*-form is ten times as effective as the *d*-form. Ethionine, which differs only by a CH_2 group, will even decrease the rate of growth in the absence of the sulphonamides, and this decrease is overcome by methionine; several of the homologous α-amino acids show a similar effect, which in two instances also is opposed by methionine. These observations suggest competitive activity for an essential enzyme, with methionine as the natural substrate and ethionine as an antagonist, just as *p*-aminobenzoic acid is the natural substrate for the enzyme system which is antagonized by the sulphonamides. To explain the inhibition of sulphonamide activity by methionine, Kohn and Harris suggest that the methionine phase of metabolism is secondary to the *p*-aminobenzoic acid phase, and that there may be a number of such stages in the essential metabolism of the bacteria. Thus, although the presence of sulphonamides blocks the *p*-aminobenzoic acid phase, the addition of a variety of inhibitors, such as methionine, might fill up the exhausted reserves at a secondary stage and enable the processes vital for growth to continue.

If this idea should prove correct—and it will of course require adequate confirmation—it is easier to see how bacteria can become " drug-fast " by elaborating their own " inhibitors " (really the normal substrate) at the secondary stage by a reaction which will by-pass the blocked primary stage; and the presence of an excess of such inhibitors in pus would explain the inactivity of sulphonamides there. Moreover the elucidation of bacterial metabolism in this way will lead, it is hoped, to the elaboration of new chemotherapeutic agents which can upset other phases in the metabolic cycles of bacteria.

THE BED-BUG

The report of the Medical Research Council's Committee on Bed-bug Infestation for the period 1935–40 has just been issued.[1] It includes six articles dealing briefly with the life and habits of the insect and with methods of combating infestation. Briefly the main conclusions are as follows. Temperature, more than any other physical factor, governs the life of the bed-bug. In an unheated room in Britain it is too cold during about one-half of the year for activity or breeding. There is a high mortality in winter, and by the spring the population consists mainly of adults and large nymphs. Control methods at this season should be most efficacious, as there are fewer bugs to kill, and living eggs (the most resistant stage) are entirely absent. No chemical fumigant is perfect; heavy naphtha has certain advantages, but cyanide is still the most efficient substance. Cleanliness on the part of the housewife will alone reduce even a serious infestation to negligible proportions, particularly if advice and direction from competent officers are available. Attention to certain details in building will produce buildings with few harbourages, and in which it will be difficult for bed-bugs to establish themselves. If public health authorities are able to apply the recommendations of this report they should be able to make real progress against bed-bug infestation. But once again it is clear that education of the general public to ensure their whole-hearted co-operation is essential before these domestic parasites are likely to be exterminated. There is no easy way to achieve this end; it will require perseverance and hard work from all parties concerned.

STERILIZATION OF DRY POWDERS

A brief account has now appeared[2] of the recent case in which fatal tetanus was believed to have been caused by the local application of unsterile sulphapyridine powder. The case is also referred to in a letter from Miss G. M. Sandes in our issue of July 18. The powder was scattered in the pelvic cavity during an operation for pyosalpinx, and tetanus developed seven days later. *Cl. tetani* was cultivated post mortem from pelvic tissue, and non-toxigenic organisms of similar morphology were cultivated from the material of two cardboard containers of sulphapyridine, and from the drug itself in one of them. The evidence is not conclusive that the infection was of this origin; it does not appear to have been proved that the organisms found were in fact *Cl. tetani*, and it is mentioned that catgut was used in the operation. There are nevertheless ample reasons for concluding that tetanus could be so produced; cardboard and coarse paper are notorious for harbouring sporogenous bacteria, and have been implicated in disasters of this kind before. The container in question bore a label stating that the contents had not been sterilized, and a representative of the manufacturers, giving evidence at the inquest, recommended that sulphapyridine powder for use locally should be sterilized by dry heat at 160° C. for 20 minutes. Presumably the more usually employed temperature of 140°–150° C. for one hour would be equally effective, but it should in any case be more generally known that temperatures of this order are necessary for sterilizing dry powders and many other materials which cannot be penetrated by steam. There is a common impression that autoclaving will sterilize anything, but the temperature attained—usually not over 120° C.—is only effective in the form of moist heat, and serves only for such materials as watery fluids and fabrics. A powder in a closed vessel is subjected only to dry heat at this temperature, and the temperature required for the sterilization by dry as distinct from moist heat is many degrees higher. If, on the other hand, the powder is in a thin layer, and fully exposed to steam, it may be possible to sterilize it by autoclaving, as suggested by Dr. J. C. Cherry in our correspondence columns this week. The same argument applies to non-watery fluids such as liquid paraffin, and it might have been supposed to be true of tulle gras until R. M. Savage[3] showed recently in this *Journal* that autoclaving unexpectedly does sterilize this material, partly because it is not quite dry and partly because it contains something chemically bactericidal. A gas or electric hot-air oven is a simple piece of sterilizing apparatus too seldom found among surgical equipment; the only place furnished with it is usually a bacteriological laboratory. It provides also an admirable method of sterilizing any glassware, including all-glass syringes and most kinds of instruments.

HEREDITARY FACTOR IN CARDIOVASCULAR DISEASE

The premature death of Raymond Pearl must have brought to an end some of the multifarious activities which he initiated. But he was the founder of an active school, and it is satisfactory to know how much is being carried on by his associates and pupils. One project, incomplete at the time of his death, has been carried to completion by A. Ciocco[4]: this was an attempt to throw light on the constitutional factor in cardiovascular disease. The extensive material was composed of copies of the death certificates of a sample of life-insurance holders who died between 1937 and 1940, together with records of their medical examination and family history obtained at the time of application. Out of 11,000 cases those chosen for study were persons whose parents were dead at the time of application, the causes of death being stated in specific terms; the cause of death of the policy holder had also to be unequivocally stated. Only white males, were included. These criteria were satisfied by 2,309 records. In drawing conclusions from this sample it has to be remembered that the group is far from representative of the general population, and that age at the time of application was, owing to the criteria adopted, considerably above the average. Nevertheless, there does not seem to be any reason for rejecting the striking positive findings at which Ciocco arrives. The percentage of policy holders who died of cardiovascular diseases was 54.3, compared with 43.0 at age 30 and over in the country as a whole. Too much cannot, however, be read into this owing to the limitations of the sampling. Duration of life was slightly but significantly longer among the cardiovascular group than among those dying from other causes. Of the parents of those dying from cardiovascular diseases 31% of the fathers and 29% of the mothers died from the same cause, as compared with 26% and 23% respectively among the parents of the remainder; these differences are significant. The really striking result, however, is the difference shown when the parents are classified according to whether neither, one, or both died from cardiovascular disease. When both parents died from other causes the percentage of policy holders dead from cardiovascular diseases was 51; when the father died from this cause, 57; when it was the mother, 56; and when both parents died of cardiovascular disease the percentage was no less than 65. This study, therefore, supports the hypothesis that innate biological constitution is a factor of much importance in the aetiology of these conditions. Ciocco ends by pointing out that the recognition of hereditary constitution as an important factor does not mean that selective breeding is the only sensible preventive measure. As in other instances, this knowledge should be a warning of the need for observation and care when the family history indicates that the patient is more likely than the average to be susceptible to a particular disease.

THE MIND OF THE CRIPPLE

A conviction is slowly permeating the minds of those who care for physically disabled persons that, just as Napoleon found in war, so in orthopaedics, the moral factor is to the material as three to one. If the patient's psyche can be induced to work in harmony with the surgeon and the physiotherapist, recovery is accelerated and made more sure. The patient co-operates in the treatment and supplies that activity and determination without which results are at best mediocre. A valuable contribution to the understanding of the mind of the crippled child has been made by the Child Guidance Council in an excellent pamphlet[1] based on three lectures given to the nursing staff of an orthopaedic hospital. The first two lectures deal with mental deficiency and with backwardness, but perhaps the most illuminating is the third, on those emotional reactions of the cripple which may make him unhappy, difficult, or antisocial. Emotional stability is essential for a good adjustment to life, but nothing is more elusive than the formulation of its ingredients. The pamphlet impresses on the nurse the vital truth, too often forgotten, that the greatest enemy of the emotions is fear. The allaying of fear, it points out, is even more important in an orthopaedic hospital than elsewhere, because the infant paralysed or confined in splints can do nothing to escape from a threatening situation. The ward should therefore not be kept quite dark, and the nurse should be quick to detect the first sign of fear in a child patient and comfort him and restore his security. To avert fear of falling, a child should be securely tucked in. He may fear suffocation from bedclothes and may fear strangers; the nurse's duty is to protect him from these fears and to establish herself as a mother-substitute as efficient as possible. An initial lack of self-reliance is especially intensified by illness affecting the use of limbs, and by anything which makes difficulties for the child or marks him out as different from others. Removal from home is a potent enemy of security. It is obviously not possible for every nurse to unravel complicated emotional problems; these are material for a child guidance clinic. What she can do is to reassure him and give him affection, to interest him and stimulate him so that he will determine to beat his handicap and make good. She will treat the aggressive or disobedient child with patience and understanding, and, most important, she will be loyal to her colleagues and superiors and not let the child play off the members of the team one against another. Dr. Anaple Christie, writing in the *Journal of the Chartered Society of Massage* for last January, also stressed the vital need to work for the child's emotional stability, to treat him as an individual, and to develop his initiative and sense of responsibility. Her paper and this pamphlet have paved the way for the systematic instruction in psychology which will soon be recognized as indispensable in the education of every orthopaedist and medical auxiliary.

PITFALLS IN "REMOVAL FOR MENTAL OBSERVATION"

BY

ARTHUR HARRIS, M.D., D.P.M.

The general practitioner is often called upon to see patients who are showing acute mental symptoms and to advise as to whether their removal to the local observation ward by the relieving officer is indicated. The conditions under which the examination is made are often adverse; there may be considerable confusion and turmoil, and a calm, unhurried appraisement of the case may be difficult. In these circumstances it is not surprising that not infrequently mistakes are made which become obvious in the calm, orderly atmosphere of the hospital. The object of this paper is to consider in the light of experience the snags which the practitioner is most likely to encounter and the chief errors likely to occur, although it is very far indeed from being comprehensive.

The main danger lies in the patients in whom the mental symptoms form part of some severe organic disorder. Many organic cases are eminently suitable for admission to observation wards, and indeed the behaviour of these patients may make this the only practicable method of dealing with them; but a consideration of the cause and of therapeutic possibilities may suggest an alternative means of disposal. The underlying trouble may be completely missed, with resulting complaints from the relatives that the patient has been treated as a lunatic instead of as a sick man.

A great safeguard against this type of mistake is the ability to recognize the "organic" mental picture, which, although described in detail in textbooks of psychiatry, including the psychiatric sections of general medical textbooks, seems to be not nearly widely enough appreciated by the profession. Curran and Slater, in the *Lancet*, 1935, 1, 69, pointed out that physicians often are ill equipped to analyse mental symptoms and lacking in special knowledge of them. For example, a young man the outstanding features of whose condition were failure of memory and disorientation in time, so that he went for his dinner when he should have gone home, and forgot which job he was working on—typical organic symptoms—was regarded as a case of functional insanity by several people, including a junior neurologist, because he showed no neurological signs. Precious months were therefore lost in the treatment of his general paralysis, and all hope of cure vanished.

Signs particularly indicative of an organic origin are memory disturbances with their corollary, disorientation in space and time. Mistakes in identities often occur, and the patient may believe the physician to be a relative or a friend of his or someone who has treated him previously. Excessive concentration of attention or preoccupation with anxieties or abstract ideas of the "absent-minded professor" type is not accompanied by true memory disturbance.

Toxic and Infective Conditions

Most infections may produce delirium, and there is no direct relation between the severity of the mental symptoms and the degree of constitutional disturbance. Alcoholic subjects are peculiarly liable, and, in them, mental symptoms tend to make their appearance early. Pulmonary conditions, cases of typhoid, endogenous intoxications such as uraemia, and a heterogeneous miscellany of febrile states frequently find their way into observation wards for this reason. The general aspect of the patient and the presence of fever and of distinctive physical signs should afford pointers to the correct diagnosis. Meningococcal meningitis may produce sudden furious delirium unaccompanied by fever or meningitic signs. In such cases the history will usually provide evidence of diagnostic value in the shape of prodromal symptoms of a few hours' or a day or two's duration, such as headache, vomiting, and pains in the limbs. Now that sulphapyridine is tending to supplant serum in treatment it is not nearly so detrimental to the interests of the patient to send him into the observation ward instead of to a fever hospital, and he can be nursed there quite satisfactorily. A good example of the type of meningitic case which gets into the observation ward is afforded by a married woman who complained to her husband, an A.R.P. worker, of nausea, general malaise, and pains in the limbs just before he started off for a twenty-four-hour shift. He thought that she had "flu," and advised her to stay in bed until he came back. On his return he found their flat in great disorder and his wife rushing about wildly, with her clothing disarranged and babbling incoherently.

Cases of neurosyphilis showing mental symptoms are usually most satisfactorily treated in mental hospitals, and removal to the observation ward in the first place is therefore not contraindicated. Alcoholic confusional and hallucinatory states are also satisfactorily dealt with in the observation ward.

Organic Lesions of the Brain

Numbers of patients with organic cerebral lesions, who would be better sent into general hospitals in the first place, find their way into observation wards; and cases of tumour, both primary and secondary, various vascular conditions, and disseminated sclerosis have passed through my hands in this way. The importance of not regarding absence of neurological signs as indicating absence of organic disease and of recognizing the type of mental disturbance produced by organic conditions is to be stressed. In one case a woman became forgetful and would go into a shop and fail to remember what she wanted to buy there. Her amnesia and confusion increased, but her doctor did not suspect serious disease until she became aphasic and suffered from transient losses of consciousness. She became comatose and died in the observation ward, post-mortem examination revealing a large highly malignant glioma.

In two rather difficult cases there was sudden collapse, after which the patients remained mute although conscious and aware of their surroundings. Both were sent in with a diagnosis of hysterical mutism, but the development within the course of a day or two of a right-sided hemiplegia rendered this untenable. Careful consideration of the history and the circumstances in which the collapse occurred would have prevented the mistake. To arrive at a diagnosis of hysteria purely by exclusion is unwarrantable. The condition is one which presents definite clinical features and a characteristic history and mental state, well described in the textbooks. The dramatic nature and mode of onset of the symptoms; the possibility of their being of some value to the patient by providing him with a solution, albeit an unsatisfactory one, of his difficulties; his emotional attitude to the symptoms; and the tendency in his previous personality to seek the limelight and to create an impression, are important.

Cardiac Failure

The confusional and delirious states associated with congestive cardiac failure are usually transitory and clear up dramatically when the primary condition is adequately treated. It is a mistake, therefore, to rush these patients off to the observation ward in the early stages of their illness if this can be avoided, although a certain small proportion will fail to respond to treatment and become chronically psychotic, in which event removal to a mental hospital may be indicated.

Reaction to Severe Physical Pain

The behaviour of some emotional individuals during an attack of severe pain may be so uncontrolled as to appear completely mad. For example, a doctor was called to a house and was told that a young man who had been visiting a friend there had suddenly been taken ill while his friend was out. When he went into the room the patient clutched his hand desperately and mumbled inarticulately, and was quite incapable of coherent speech. The doctor not unnaturally concluded that the man was insane, and sent for the relieving officer. On arrival at the observation ward the patient appeared quite normal, but stated that he had just had some dreadful pains and described a typical attack of renal colic. When they found out the nature of the hospital to which he had been sent, both he and his family expressed great indignation, and one cannot help feeling that the doctor's reputation in the district suffered considerably as a result of this unfortunate incident.

Failures of complete diagnosis such as those described above are easily rectified and rarely prejudice the welfare of the patient: at the worst they involve him in an unnecessary journey between hospitals, but they are somewhat mortifying to the keen practitioner who prides himself on his professional skill. The patients and their relatives often attach undue importance to these failures because of the faulty attitude of the general public towards mental disease and the sharp distinction which they draw between it and physical disease.

The mistake of removing a person to the observation ward on totally inadequate grounds is not commonly made. Foreigners with little or no knowledge of English are sometimes the victims. I remember particularly a voluble, excitable harbour official from Dunkirk whose behaviour following upon the stress of the evacuation caused unnecessary alarm to harassed refugee reception centre officials accustomed to British phlegm and unfamiliar with the more mercurial temperament of our Latin neighbours. Mere eccentricity or even delusional beliefs in the absence of definite antisocial trends are no grounds for interference with the liberty of the subject. One of my patients was a woman with queer hypochondriacal and religious ideas; but the former were derived from old country superstitions, and the latter were shared by other members of the exotic sect to which she belonged, so there was no justification for regarding them as evidence of insanity.

Delinquents, both children and adults of low intelligence, are sometimes sent for observation. No harm is done thereby, since such people present psychiatric and psychological problems, but they are usually better dealt with in the out-patient clinics which exist for the purpose in most large towns.

The patients for whom Section 20 of the Lunacy Act of 1890 is intended primarily are those whom it is fairly urgently necessary to put under control and restraint. In delirious states especially this urgency is usually much reduced by the administration of 2 drachms of paraldehyde or of a similar drug. The question of suicidal risk in depressed patients is the most difficult one facing the physician in this respect. Co-operative patients who can be dealt with in a more leisurely manner may be brought under treatment by other means. Subjects of functional psychoses can be seen in psychiatric out-patient clinics, and from there, if necessary, arrangements can be made for them to enter mental hospitals as voluntary patients. Cases of suspected tumour and other organic neurological disorders can be sent to general or neurological hospitals for diagnosis and treatment.

I am indebted to Dr. O. W. Roberts, medical superintendent of St. Francis Hospital, and to Dr. Allen Daley, medical officer of health to the L.C.C., for permission to publish this paper.

LEPROSY IN THE COLONIAL EMPIRE

Lord Moyne, formerly Secretary of State for the Colonies, presided over the annual meeting of the British Empire Leprosy Relief Association. Sir William Peel, chairman of the executive committee, in reviewing the work of leprosy control and cure in the Empire, so far as it can be made under war conditions, mentioned the appointment by the Association in 1940 of three doctors to Nigeria, a step which had proved most beneficial to the leper colonies at which they were stationed. The work in this territory was gradually extending, but the estimate of the number of lepers remained very high, though this might be due to a growing readiness of patients to come forward rather than to an actual increase in the number of cases. From the colonies now in enemy hands reports had come of inspiring devotion to duty. Sir William mentioned the leper settlement at Sungei Buloh in the Federated Malay States, perhaps one of the finest settlements of its kind in the world, where its head, Dr. G. A. Ryrie, had remained at his post during the occupation of the colony by the Japanese, and had been requested by the Japanese to continue his work. He added that the Association had offered financial help to this settlement, should it be needed, as soon as contact through the Red Cross or otherwise was made.

An address was given by Dr. H. G. Anderson, medical secretary of the Church Missionary Society, who said that in view of the wide publicity it had received it was rather sad to have to record that the diphtheria toxoid treatment of leprosy had not fulfilled the early claims made for it, though a negative result of this sort had its value. No praise could be too high for the biochemists who had explored the field of synthetic chemistry. By the yardstick of history their work was still young, but the pace was quickening, and their triumphs were only the first indications of great possibilities. One problem facing the association in the future was that of still further aid to and liaison with the laboratory. He thought the first step should be an enlargement of the association's clinical staff, for, after all, it was the clinician who was the senior partner in the association between medicine and the biochemists. It would be wise, after the succession of frontal advances in their work, to consider seriously the more adequate consolidation of the bases created over-seas. As a first move he suggested the doubling of the staff of qualified doctors. With such an addition the survey and clinical laboratory work would automatically be able to take their vital share in the attack on leprosy.

ANAEMIA IN X-RAY WORKERS

A number of workers in *x*-ray departments in E.M.S. hospitals have been taken off work because they were considered to be suffering from minor degrees of anaemia due to the effects of *x* rays. Such action, states the Director-General, E.M.S., in a letter to Regional Hospital Officers and Sector Hospital Officers, is unnecessary, as the anaemia from which these persons may be suffering is almost certainly not due to the specific action of *x* rays. In order to allay any uneasiness and to guide hospitals in the treatment of such cases, it is asked that the information in the following note on blood examinations in *x*-ray workers be passed on to all E.M.S. hospitals with *x*-ray departments.

Blood Examinations

Periodic blood examinations of *x*-ray workers have been carried out in many institutions over a long period of years. Many such records are available. In none of these institutions has a single case of aplastic anaemia occurred, and there appears to be no record in the literature of aplastic anaemia developing in any *x*-ray worker who was not also in contact with radium.

A few cases of ordinary secondary anaemia are found from time to time, and these appear to result from the conditions of employment rather than from any specific action of the rays. Very rare examples have been met with in which the white cell count has been seriously reduced, but recovery has taken place after a short absence from work. One interesting and apparently extremely rare example has been observed at King's College Hospital of a girl who, on return to work, developed a severe leucopenia for the second time and was advised to find some other occupation.

It seems generally agreed that periodic blood examinations—at intervals of 6 to 12 months—are advisable as a means of detecting haemoglobin and red cell deficiencies in persons working under unfavourable surroundings, of discovering the very exceptional *x*-ray worker who may develop serious white cell deficiency, and as a reassurance to radiographers in general. It is also a reasonable procedure to make a blood examination of all candidates for employment in an *x*-ray department before they start work. Minor degrees of anaemia need not be treated more seriously among radiographers than similar conditions in other occupations. Minor degrees of leucopenia should suggest a further examination at a short interval—e.g., two weeks—and if confirmed and progressive should entail removal from work until the blood state is re-established and the count found to remain constant.

The term "*x*-ray anaemia" has no particular meaning and should be avoided.

Eleven distinguished medical men, representing the home country, the Dominions, and the United States, have been elected to the Honorary Fellowship of the Royal Society of Medicine at a special meeting. The two from the home country were Lord Horder and Sir John Herbert Parsons, a former President of the Society. The two from Canada were Prof. W. E. Gallie, Dean of the Medical Faculty of the University of Toronto, and Prof. Jonathan Meakins, Director of the Department of Medicine at McGill. The two from Australia were Sir Charles Blackburn, consulting physician, Royal Prince Alfred Hospital, Sydney, and Sir Hugh Devine, Lecturer in Surgery at the University of Melbourne. New Zealand and South Africa each had one representative—namely, Sir Henry Lindo Ferguson, Professor of Ophthalmology and Dean of the Medical Faculty, Otago University, and Dr. A. W. Falconer, Professor of Medicine at the University of Capetown. The three medical men in the U.S.A. were Dr. Hugh Cabot, consulting surgeon at the Mayo Clinic, Dr. David Cheever, Associate Professor of Surgical Anatomy at Harvard (who had charge of the Harvard Surgical Unit which was sent to the Western Front in 1915-16), and Dr. W. T. Longcope, physician-in-chief, Johns Hopkins Hospital, Baltimore.

Correspondence

The Teaching of Anatomy

SIR,—The correspondence which followed our letter, published in your *Journal* on Feb. 7, 1942, on the teaching of anatomy, shows a substantial measure of support for our opinion that an anatomical curriculum of greater educational value could be provided if there were a reduction of descriptive detail in the general course.

Time is needed in the curriculum for a broad education in structural organization with its functional implications, and the subject-matter should be selected from a wide field. A knowledge of the requisite descriptive detail should be built up on this basis. For example, it is of far greater value to the student that he should learn the plan of construction of nerve plexuses through an understanding of the nature of that plan rather than by memorization of a system of apparently arbitrary interconnexions. There should be a sound knowledge of the differentiation and growth of tissues, and the study of histological detail should be concurrent with that of gross structure.

We agree with those correspondents who have drawn attention to the extensive changes that have taken place in the curriculum during the twenty years that have elapsed since Prof. Berry's contribution to your *Journal* (Jan. 15, 1921), to which reference was made in your leading article of March 21, 1942. These changes, which have been already introduced in the anatomy departments of many medical schools, have been noteworthy for the increasing emphasis which is laid on the study of the living subject and for the variety of methods employed. Again, there has been more pruning of minutiae than is realized by some commentators, who depend on their own recollections of education in the past, or on a consideration of the needs of their own particular specialization.

Further reduction of descriptive detail will concern some systems more than others, but it cannot be effected, as has occasionally been suggested, by the complete elimination of some region of the body from the course of dissection. From our experience as teachers we are convinced that attempts to learn from previously prepared dissections do not replace the advantages of personal dissection, and there is a loss rather than a gain of time in the attainment of a given standard. We agree, however, that for the purposes of the ordinary M.B. student certain parts of the body do not require to be dissected in great detail.

In your leading article you expressed the hope that effective action will follow without delay. We concur in this view. While there may, in the near future, be some redefinition of the scope and functions of the practitioner, with a consequent change in the requirements of the curricula in anatomy as well as in other subjects, we feel that the ventilation of opinions which has been privileged in your *Journal* will have served to assist in further action.—We are, etc.,

ARTHUR B. APPLETON.

"Positive Health"

SIR,—The first object of medical service, says the Planning Commission, is to provide a system directed towards the achievement of positive health. The phrase is not defined. That achievement, clearly, must be by prevention. I thought of Surg. Capt. D. H. C. Given's letter (Dec. 27, 1941, p. 928) that 87% of the teeth of the Indian coolie labour recruits at the Singapore base were perfect, whereas the corresponding figure for our own naval ratings was only 2.75%. Something had prevented abnormal dentition, overcrowding, and decay of the Asiatics' teeth, something operative before the seventeenth week of their mothers' pregnancy. I thought, too, of a remark in a letter received from Dr. Scharff of Singapore: "The war had given us the long-wished-for opportunity of trying out the wholesale distribution of 'husked rice' to the natives of Malaya. In the areas studied this measure had halved our infant mortality (160 per mille dropped to 80!) largely because of its effect on the improvement of health in the mother." And it seemed to me that the "medical service directed towards the achievement of positive health" must be mainly preventive, and, moreover, mainly dietetic; and clearly, too, the mother's diet has, in many respects, settled the constitution of the individual as many years as he has lived, and more, before he presents himself to the ordinary practising doctor as a patient. Which brings us to this—that we must take thought how to advise the mothers and potential mothers about their food. What a task!

I tried to ascertain from the chief figures of the Planning Commission whether something of this sort was in their minds and was behind the words "positive health." They neither confirmed nor denied it. But surely nothing less will suffice. Dr. Innes Pearse of the Peckham Health Centre is more forthcoming in your issue of July 18 (p. 78). She takes the words to imply early recognition of disease and then change of environment: "Nothing but periodic overhaul can disclose the disorders of those unaware of their presence," and "it [the overhaul] must be accompanied by circumstances which enable the family . . . to move out of the environment that has created these disorders into one in which they live and function more fully—i.e., in health." She is speaking, doubtless, from her invaluable experience of the Peckham Centre; and as I understand that dietetics and, more than that, the proper growing of the vegetables constitute essential features of its work, there is no doubt that "environment" includes the source, quality, and choice of the food supply.

Dr. Pearse points to the knowledge of the man in the street that "hospitals and clinics, which have a 'corner' in scientific instruments, without which he presumes that the medical services cannot do justice to the nice demands of non-incapacitating disorder, will almost inevitably immobilize him should he go near them"; and advocates, not the periodical medical overhaul of individuals, which, even if it were accepted, would have a bad effect on the mind, but the periodical health overhaul of the family. This she has carried out with 2,000 families, it seems, in the great experiment at Peckham. Admirable, detailed, laborious work, giving attention to a multitude of points. And, of these, some few are paramount; from the long-term point of view one, food, not only its nature but its quality. The old rowing coach used to say: "At each stroke you must bethink you of 32 maxims; but if you carry out 3 of them the rest are automatic." So with nutrition. With the best wish for the continuance and spread of the pioneer work of Dr. Pearse, I feel that nutrition is the chief weapon in her and our crusade for "positive health"; and, moreover, is one which can be carried into fields not ripe for a system of "periodic overhaul."

To be more precise about the "quality" of food I would illustrate it by the article by Rowlands and Wilkinson on "The Vitamin B Content in the Crop" (*Biochem. J.*, No. 1, 1930). Having noticed that pigs on home-grown barley and wheat did better than on bought, they fed two groups of rats upon grass and clover seeds, manured respectively with dung and chemical manure. The upshot was that those on the former grew nearly twice as well as those on the latter. As a brilliant little book by Mrs. Grant says: "The question of fertile soil affects the housewife much more deeply than is at first realized" (*Feeding the Family in Wartime.* Foreword by Lord Woolton. Harraps).—I am, etc.,

LIONEL JAS. PICTON.

Holmes Chapel.

SIR,—I am glad to find the meaning of "positive health" questioned by Mr. A. R. Jordan (July 4, p. 22). Quoting from the aims set forth by the Medical Planning Commission in its draft interim report, he infers that the term stands for "health at or above the average." He errs; for its warm advocates on the Commission define it as high-grade physique. This corresponds exactly to the alternative definition Mr. Jordan mentioned and deplored at the close of his letter—namely, "exuberant health." A few members strongly objected to the adjective "positive." I am disappointed to find no response to his lead, as I fear that, if the term is retained, it will appear ludicrous to our successors.

When the aims of an issue so great as the physical salvation of a nation are stated, journalese should be avoided. Let us, at the opening of this great campaign for health, use a term whose meaning is readily grasped and so avoid speculation in the minds of readers. If we want ambitiously to stress fine physique for all, we may say in plain English "abundant health." But as such an ideal does not come within the range of practical politics, should we not be content with stating merely "health for all" as our aim? Our descendants will still be struggling to attain even that 100 years hence.

The majority of the nation lack health at present, and in many ways—major and minor. Let us consider a few hard facts. We may fairly assume that the Army which went to France in 1939 was composed of the best of our young manhood, yet no less than 87% of the recruits needed dental treatment and 12% of the total were found to require dentures. A large percentage of children suffer from tonsillitis and apparently require operation. So much for the commencement, while, at the other end of the alimentary canal, constipation and piles are the bane of hundreds of thousands. Varicose veins and foot troubles are very common. The truth is that millions of our population are afflicted with more than one of the foregoing minor ills. Among major maladies peptic ulcer is so common and affects men in the prime of life. Evidence on this also has been provided by the war, for of the sick evacuated from France 12% had peptic ulcer. In later life cancer causes what is often a cruel ending to the lives of some 70,000 a year of our population, and the total crippling and pain inflicted by rheumatism makes another hideous mountain of wreckage.

On reflection, it seems well to approach with circumspection and humility such a stupendous task as the replacement of widespread disease by universal health. When stating our aims, let us not be Utopians but explicit and realistic, as becomes men of scientific training.—I am, etc.,

Bristol A. WILFRID ADAMS.

Primary Medical Interests

SIR,—Your correspondence on "Positive Health," "Social Medicine," and "Health Centres" has become even more interesting than usual. I am not sure, however, that advocacy of a thorough-going State service is going to serve the real needs of positive health, which, I venture to think, is a spiritual, mental, and genetic problem once the elementary fundamental need of a good environment is satisfied. This is not the case to-day for a large section of our people. Granted that research is needed, this takes a long time to carry out. Meanwhile it is quite obvious that, without waiting, many steps to positive health and social advance can be taken. Our post-war framework must be one which gives people room to live in, not only in their houses and gardens but in the arrangement of their houses in relation to one another.

I have never understood why the family and the home is not of primary medical interest, and if it is political (I am not a member of the Socialist Medical Association) then we must all take an interest in politics, though not necessarily party politics. The same may be said about the primary needs of good food for everyone, and the great question seems to me to be how the views of the medical profession are to achieve their proper authority without getting entangled in the hurly-burly of "party" which they must keep out of.—I am, etc.,

Letchworth, Herts. NORMAN MACFADYEN.

The Planning Commission's Report

SIR,—The issue of the Medical Planning Commission's interim report will, I hope, lead to a great deal of thought and adequate discussion, and it is with this object in view that I submit these observations dealing with matters that are not adequately dealt with in the report.

1. The report pays lip service to "positive health" but makes not the slightest suggestion in connexion with its attainment. I suggest that the primary health centres should be the outposts of this service, and that a room (possibly a waiting room or hall at other times) should be available for instructional films, lectures, gymnastic "keep fit" classes, etc., etc. Cookery should be taught or else the centre linked up with existing cookery schools, and doctors should urge their patients to attend these classes as a positive contribution to the prevention of lesions of the alimentary tract. Housewifery as a contribution to environmental hygiene must be taught and encouraged; squalor and dirt are detrimental to health. Dental services must play an important part, and a more conservative dentistry encouraged among the poor; there is no mention of dental services. Propaganda will be required. The report does not mention convalescent camps or camps for jaded workers as exist in Russia.

2. The present appalling state of "industrial surgery" is rather slurred over. At present, though compensation is payable to workers suffering from injuries or diseases resulting from their occupation, no provision is made for the treatment of such cases, and to a very large extent this is left to charitable institutions to carry out under the gratuitous direction of an honorary consulting staff and the immediate supervision of an inexperienced and newly qualified resident staff. The result of this is that much of the treatment is bad and disability prolonged. There has been a tendency recently to concentrate on fractures, but no mention is made of septic hands and their crippling effects, many of which could be avoided if the knowledge already available in textbooks were applied, nor of minor muscle injuries. Moreover, if a remuneration adequate to encourage surgeons to take up this work were paid, and the subject efficiently tackled, not only would this knowledge be applied but further knowledge would soon be gained. In this connexion some reform in the way in which doctors are subpoenaed to give evidence must be achieved. At present one's work is interrupted to go miles to hang about in the discomforts of a law court, and either not give evidence at all or else merely repeat what has already been written. The least that should be done is that the doctor should in these cases only be called by the direction of the judge using his discretion, and the power to issue a subpoena should not be vested in any solicitor. It is this side of the matter as well as the absence of remuneration that makes keen surgeons avoid dealing with these cases, as they dislike being mixed up in the sordid atmosphere of the courts. Other causes of industrial casualties such as hernias, etc., are for similar reasons too often left to the inexperienced. The need for reform in dealing with all these cases is urgent. The number of man-hours saved would be enormous if these industrial casualties were efficiently treated, knowledge pooled, and a statistical check kept on the period of disability in assessing the value of the methods employed.

3. Teaching hospitals cannot be regarded as the pinnacles of clinical medicine. For one thing the selection of staff is too haphazard. Social or athletic attainments may play too great a part in appointments. For one vacancy there may be many applicants, and even supposing, as we are not inclined to do, that the best candidate is always appointed, the others may be much above the average and seek posts elsewhere. When the next vacancy occurs the applicants that time may not be so good, but one has to be appointed as those previously rejected are no longer available. Further, there is not sufficient interchange, and, as a rule, the teaching hospital would sooner elect a mediocre candidate of its own school than bring in a brilliant candidate from another. A man may be elected quite rightly for his teaching ability rather than for his clinical ability, and it has been said that in the case of most teaching hospitals it would be easy to find as good or an even better staff from those who failed to get on to the staff. Nor are all teaching schools equal in any one respect. In actual practice many of the non-teaching hospitals do work of as high an order as the teaching hospitals, and again there are teaching hospitals which are more teaching in name than in practice, and only have occasional students. If there were to be a teaching hospital in each region it would mean breaking up and decentralizing the London medical school. This, of course, might be a good thing, but would carry with it, so far as the staff is concerned, the dangers of isolation and perhaps the loss of the stimulating effect of contacts with other teachers.

It has been argued in some quarters that to plan post-war medicine now is to divert our energies from the more urgent and immediate necessity of winning the war. On the other hand, one hears rumours of plans for socializing medicine, and one prominent member of Parliament in a broadcast speech boasted that capitalists would never regain the privileges they had lost during the war, while at the same time inviting them voluntarily to give up further privileges as an act of patriotism. I am not in the least concerned about the rights and wrongs of the various political ideals, but in medicine we have given up a great deal of our freedom during the war, voluntarily and patriotically, and while we may, and I hope will, be prepared to continue to do so for the public good, it would be, to my mind, contrary to all the ideas of fair play if this patriotic abnegation were exploited for party purposes, and it is for this reason that we must watch our liberties lest, while fighting the enemy, we are stabbed in the back by those who put party before all.—I am, etc.,

Hove. H. J. McCURRICH.

SIR,—There is an aspect of the interim report of the Medical Planning Commission which does not seem to have received the attention it deserves. It appears in several places, but is most clearly expressed in paragraph 60, which says:

> "It is recognized that it will be necessary to amend the existing law in order to permit medical practitioners to act as members of local authorities while participating in the medical services outlined in these proposals."

A general principle running through the whole constitutional structure of this country is here expressed in the law relating to local authorities. It is a law which not only prevents corruption but also prevents interference with the private lives and liberties of the subject, and it is surely unlikely that such a law can be altered as easily as the paragraph quoted would suggest. Also, there is no reason why an exception should be made for the medical profession, and claims for similar representation would soon be heard coming from other professions such as engineering, surveying, and even from the trades. It must equally well be realized that if the law cannot be altered there can be no medical representation.

The point appears again in paragraph 58 by including in the Regional Councils "an adequate representation of the medical profession." If the Regional Councils are to constitute a new series of bodies independent of local authorities, a series of fresh laws would have to be enacted to cover them. Again, it is unlikely that Parliament would create a new law transgressing a principle almost as fundamental as that of the Habeas Corpus Act in protecting the liberties for which we are fighting by preventing the setting up of a dictatorship.

The position should be made clear by an authoritative statement from persons with high legal and political qualifications before any further castles are built upon a foundation of political sand. If some such statement could be made as that "there could be no medical representation in control of a State Medical Service that included the whole or a substantial proportion of the profession," then medical opinion might be much more unanimous on many controversial issues mentioned in the interim report. My own opinion, for what it is worth, is that a Regional Council containing interested medical representation would soon lose all power and become advisory in character.—I am, etc.,

London, S E 3. J. E. STOKES.

Treatment of Haemophilia

SIR,—The paper by Messrs. C. L. Endicott, J. H. Mitchell, and G. Qvist (July 11, p. 34) shows so great an unfamiliarity with the modern treatment of haemophilia that we hope that it does not represent the views of the average dental surgeon. Calcium and citrous fruits certainly have no part in that treatment, but it is quite wrong to advise the dental practitioner to "direct his efforts at controlling haemorrhage to local application of demonstrably effective agents rather than to speed up the coagulation processes by systemic medication." The value of fresh blood transfusion in haemophilia has been known ever since blood transfusion became popular, and more recently the value of plasma and derivatives thereof has become appreciated. Johnson's[1] results with lyophile plasma are particularly striking. When a haemophiliac needs dental treatment—and many of them do—he should be admitted to a hospital under a medical man who understands the disease. It is essential not to underestimate the threat of haemophilia before the operation or to overestimate it afterwards. Provided the patient has good veins for transfusion he should not die from a bleeding tooth socket. In the case reported the bleeding was a slow capillary ooze. Experience suggests that replacement of the blood lost would not have necessitated transfusion more often than every other day. Yet because of excessive concern over the local lesion, a relatively harmless external bleeding was converted into a fatal internal bleeding for the anatomical reasons which the authors have so clearly demonstrated.

Local treatment was discussed in detail by one of us in 1935.[2] It was pointed out that "closing the skin over bleeding-points which cannot be controlled is bound to lead to an extensive haematoma." Nothing but harm can come from over-zealous local treatment. A dressing soaked in Russell's viper venom combined with firm pressure applied for 5 minutes will usually stop bleeding for 2 to 24 hours. In our last two cases Parfentjev's[3] thrombin was even more successful. The intervals between bleeding become gradually longer till the haemorrhage ceases. Those familiar with haemophilia know only too well asphyxia produced by haemorrhage into the floor of the mouth, and infiltration into the planes of the neck is one of the most dreaded complications. To sew the gum over a bleeding socket is to invite this complication. It is our hope that the facts so clearly presented in Endicott, Mitchell, and Qvist's paper will effectively discourage measures of this kind in the future.—We are, etc.,

SIR,—One of the comments to the article in your issue of July 11 (p. 35) contains the following: "It is doubtful if in the present state of knowledge it is possible to take adequate pre-operative measures to control haemorrhage in haemophilia." I wish to make a direct challenge to this statement.

In 1936 I discovered a remedy for haemophilia which was announced to the profession in the *Lancet* of Nov. 14 in that year. The discovery was then in its first stages. Continued research has enabled me to produce a substance which will lower clotting-times in haemophiliacs and in normal persons, and will arrest bleeding, whether internal or external. In my book *Haemophilia and Egg-white Derivatives*, and in the *Lancet* paper referred to, I gave details of over 60 teeth extractions in haemophilia, and on page 3 of the book I pointed out the dangers of local interference. My work has been verified clinically by other doctors and by clotting-time determinations, and so recently as five weeks ago a pathologist used my anti-haemorrhage material on a patient who had a spreading haemorrhage into the neck and was unable to swallow solids. The pathologist wrote: "When I gave him 2 c.cm. of your preparation intravenously yesterday I was astonished at his improvement; to-day he got up and was able to eat."

In my opinion, teeth extraction in haemophilia is a simple and safe operation if my material is used. It can be given prophylactically as well as against actual attacks.—I am, etc.,

Narco-analysis in Treatment of War Neuroses

SIR,—I was very interested in Major J. F. Wilde's article (July 4, p. 4) describing his results from the use of this method in 50 cases. During the past 15 months I have had experience of the treatment of 200 such cases and cannot share his enthusiasm.

I have always been impressed by the fact that nearly always no further information was obtained by using the drug than was already available from ordinary conversation, provided one departed from the more formal type of interview and met the patient half way. If, after listening to the patient's description of his symptoms and excluding organic disease by every possible means, the doctor explains that he is not really a sick man but an unhappy one suffering from some thwarted desires, which the doctor sympathizes with and would like to help with if he can regard the doctor as his friend, the patient will almost always respond with an emotional reaction, usually accompanied by tears and a confession of the truth of this statement. From this moment the flood gates are open and by simple questioning most of what one wants to know can be ascertained, not only about his present difficulties but also his more remote worries and private affairs, and this state of "rapport" once established will persist throughout subsequent interviews.

This latter fact is important as the doctor is not merely seeking information but trying to effect a cure, and for this purpose a satisfactory transference is necessary, a factor I have often found lacking after narco-analysis, as the patient tends to return to his former attitude, and when this is accompanied by the usual mild degree of amnesia for the period of anaesthetization he may minimize the significance of the statements he has made and would like to deny them. For example, I had a patient who admitted inverse sex feelings in the early part of his life, and from my questioning I had little doubt that his present depression was associated with a persistence of these feelings, but he maintained that he had "put all that away." Under the influence of pentothal the correctness of the diagnosis was confirmed, but when seen the next day he scoffed at the idea and was sure that it was only the drug which "made him talk such rubbish." A confession extorted by force can be denied later by the patient if it suits his convenience, and, more important, if his "super-ego" still remains as it was.

In a large proportion of cases, however, there will still remain unconscious factors which cannot be elicited by the simple establishment of "rapport," and it is here that hypno-analysis is the ideal short cut and a real advance on the more time-consuming methods of orthodox psycho-analysis. In this matter it is astonishing how relatively easy it is to induce hypnosis in war neurotics as compared with their peacetime counterparts. In cases where this has failed I have not found any assistance from the use of pentothal. From my experience I would maintain that the latter never reveals deeply repressed material nor unmasks a true amnesia, but only a pseudo-amnesia. By that I mean that the patient really has access to the apparently forgotten material but does not wish to reproduce it, either for his own or others' inspection, because he is ashamed or frightened of it or realizes it possesses a certain value as a means to an end.

As an illustration of this point I would like to quote an example of a type of case in which I think pentothal is definitely a help—that is, an anxiety state of extreme degree in which the patient is too agitated to be able to settle to listen to an explanation of his illness. The man in question was showing extreme terror, unable to sit still during interview, and when it was suggested that his experiences at Dunkirk were a probable factor in causing his illness he said that he did not remember what happened and that, therefore, it was no use discussing it. As he was unapproachable by any other means he was given an injection of pentothal and a full account of his experiences obtained. When seen the next day he admitted that he had really been quite aware of the facts all the time but was trying hard to forget them and "did not want anyone to drag them up again." There was only slight improvement of his condition, but he was now agreeable to frequent talks about his troubles and subsequently improved enough to be fit for duty. Here the amnesia was obviously only apparent, and the process of repression a conscious rather than an unconscious effort.

To conclude, I should like to maintain that narco-analysis should only be rarely resorted to as it is a confession that more simple methods have failed; secondly, that it is not a reliable means of effecting a transference; and, finally, that it is not a means of gaining access to deeply repressed material.—I am, etc.,

J. L. Clegg.

Consulting Psychiatrist to an E M S Hospital.

Diphtheria Prophylaxis

Sir,—In your issue of June 13 (p. 735) there appears a rather misleading statement to the effect that medical practitioners are entitled to receive A.P.T. free of cost from the local authority. It ought to be made clear that Section 177 of the Public Health Act, 1936, limits the facility to "the poorer inhabitants." These are already being treated under local authority schemes (either by general practitioners or medical officers) with A.P.T. supplied through the E.M.S. laboratories, and the obvious measure for practitioners dissatisfied with the private supply of A.P.T. is to refer patients to the local authority for treatment. Surely your statement was not intended to mean that private practitioners could obtain free A.P.T. from the local authority and charge their patients fees for administering it.—I am, etc.,

Health Department, West Bridgford. W. B. Watson.

*** We understand that in view of the vital necessity for countering the increased risk of diphtheria arising from war conditions, the Ministry of Health has arranged for the free issue to local authorities of diphtheria prophylactic, and it is urging them to persuade as many parents as possible to have their children immunized. The Ministry does not contemplate that this campaign can be restricted to any particular class of parents or children.—Ed., *B.M.J.*

Standardized Wassermann Reactions

Sir,—The discussion in your columns of this matter will advertise again the canon that the blood serum test is an integral factor in the diagnosis and treatment of syphilis; and there must be consequent insistence on the test being subject to the least possible error.

The arbiter of the worth of any test for the live patient will always be the experienced clinician, and he has long and well learnt that whenever the result of the serum test must weigh heaviest in the evidence, at the least it should be repeated. To lessen the chance of error, standardization of material reagent and of human method is an obvious step. The Medical Research Council's publications have gone far towards standardization of method, and all those who have the care of syphilis patients are indebted to Col. L. W. Harrison for the valuable service constituted in the supply by the Ministry of Health's special laboratory of tested (which surely is to say "standardized") reagents.

Dr. Orpwood Price (July 11, p. 54) tells us that three things used in the performance of the Wassermann test can be standardized—the technique, the antigen, the saline—and that the complement, the amboceptor, and the red blood cells cannot be so dealt with. In view of the supply of tested complement and amboceptor from the Ministry's laboratory, Dr. Orpwood Price's meaning is not perhaps fully apparent. However, I pose the question, Why bother any more with Wassermann tests for blood serum which require the dubbed refractory three, carrying many more chances of error than can enter into a precipitin blood serum test for syphilis, such as the Kahn or Laughlen, which require only the dubbed amenable three? Moreover, though the Wassermann test still enjoys a tacit "approval" in "approved" laboratories, many years' clinical experience has not yet detected any superior reliability or usefulness for it over the Kahn as a blood serum test for syphilis; on the contrary, in some stages of syphilis it is notably inferior. And if on top of this it is more subject—as it is—to error in any hands in any laboratory, again, what and why the inertia that underpins its "approval" as the blood serum test?

In dealing with syphilis as a public measure I put forward the axiom that the best for the patient and the public is for the medical officer in charge of the patients to have had such first-hand experience of the performance of all serum and other laboratory tests as to be able to do them again for himself if need be; that his pathologist or his, the clinician's, laboratory technician (why not?) should be at his elbow; an active though subordinate colleague in the medical care of the patient. This is hardly possible in the large clinic with the large laboratory, where the doctor and his pathologist may easily be kept too far apart, even though they be under the same roof. I maintain that because laboratory tests are integral, indispensable factors in diagnosis and treatment, laboratory and treatment rooms should be but different near-by rooms in one house, with one head of the house, who must be the medical officer actively and primarily engaged in, and responsible for, all that pertains to the proper diagnosis and treatment of the patients. He, not the staff of the treatment centre, must be the doctor. Therefore, in the major ruling interest—the patients'—"plans for the future" should provide for splitting all large V.D. clinics and large V.D. laboratories into smaller treatment centres, and for each centre of clinic-and-laboratory to be under one director.—I am, etc.,

H. M. HANSCHELL,
Director, V.D. Department,
Albert Dock Hospital.

SIR,—The point at issue is that while large numbers of laboratories carry out Wassermann tests, few can be trusted to give really reliable results. This casts no aspersion on the skill of the pathologists concerned, since it is obvious that it is only in those laboratories which carry out large numbers of tests and in which there is a close liaison with the clinical side that results can be properly checked; without such a check errors may creep in only too easily. If the Ministry of Health would publish a list of those laboratories which have been approved under the V.D. scheme, practitioners would know where to send specimens of blood in the hope of getting results on which reliance could be placed.—I am, etc.,

London, S W 1 T. E. OSMOND.

Tetanus after Sulphonamide Treatment of Cavities

SIR,—Dr. E. C. Atkinson (July 4, p. 24) has certainly proved the fallacy of the second part of the statement, "Sterilization of sulphonamide crystals does no harm but is unnecessary." I have found, however, that, although sterilization is necessary, unless care is taken in carrying it out harm is done to the crystals, and I think that the recommendation suggested of sterilizing at 160° C. for twenty minutes will prove harmful to the drug. If sulphapyridine is heated above 150° C. for twenty minutes it shows some darkening in colour. Sulphathiazole will certainly form a purple tint at this temperature, as also will sulphanilamide. This change in colour probably renders the powder toxic, and it should not be used.

I believe Dr. Atkinson is right in his statement that the powder is constantly used in hospitals without being sterilized, and I would suggest that the reason for this is that the makers have not supplied adequate information as to how this sterilization should be carried out. I have used the following technique of sterilization for the past eighteen months and have found it satisfactory; I give it in some detail in the hope that it may prove useful to others using the drug.

1. Place 15 grammes of the powder in a 500-c.cm. conical glass beaker which has been previously boiled. Plug the mouth of the beaker loosely with sterile cotton-wool.
2. Boil a glass jar in which it is intended to store the powder. (This jar may then be labelled with an ordinary gum label after the jar has been boiled and before it is placed in the autoclave. The label will remain on the jar during the autoclaving, and is quite readable, if a little discoloured, when the jar is taken out) A glass rod and a few small bowls should also be boiled.
3. All the above are placed on a large tray in the autoclave.
4. The door of the autoclave is made fast and the vacuum pump turned on until a negative pressure of 16 lb. to sq. in. registers.
5. Shut off the vacuum pump and turn on the steam. Raise steam to a pressure of 16 lb to sq. in (16 lb. pressure to sq. in.=260° F. or 126° C. approximately). This pressure of steam is maintained for 20 minutes.
6. Turn off the steam and empty the autoclave of steam The vacuum pump is turned on until a negative pressure of 16 lb. to sq. in. is registered. (The object of producing a vacuum the second time is to make sure the powder comes out dry.)
7. Shut off the vacuum pump, open the autoclave, and take out the tray. (The person taking out the tray should wear sterile gloves, gown, and mask.)
8. Place the tray on a sterile table The powder in the beaker may be slightly caked, and may need to be pounded a little with a glass rod. It will then easily be transferred into the glass jar (which has been in the autoclave already labelled). The glass stopper is placed in the jar.
9. The jar is stored in a sterile theatre drum ready for use.

If the powder before being placed in the beaker is not moistened its sterilization may not be quite so effective. However, the powder if moistened before being placed in the beaker (as recommended by some) will crystallize to a greater or less extent according to the degree of moisture achieved. On taking it out of the autoclave it will be found to have lost its nice powdery appearance. This crystallization does not alter its therapeutic value, although it may render its absorption from a wound less rapid.—I am, etc.,

Dublin. J. C. CHERRY.

Treatment of Scabies

SIR,—Advance in the treatment and control of scabies has been delayed by the element of mystery and uncertainty which has followed it down the ages. Prof. R. M. Gordon and Dr. D. R. Seaton (June 6, p. 685) have introduced a new substance which may prove to be a definite therapeutic advance. Whereas the limitations of their animal experiments were appreciated by the authors, certain of their conclusions support traditional beliefs which are now being questioned by clinical observation. The infectivity of clothing and blankets depends on the ability of the patient to infect them and is a variable factor. With the average case to-day the parasitic population is not large, and the infectivity of fomites is correspondingly low. Investigations in the last war seem to have been carried out with cases having a great number of active and potentially infective mites, and reports often placed blankets among the chief sources of infection. In cases seen over the past few months I have not yet been able to find or to expect the presence of as many mites in a case of scabies as were recovered by the above authors from the small piece of silk tied overnight to an infected rat's tail.

A hot bath, often with soaking and scrubbing of the body, is accepted as the usual preliminary to treatment. The traditional reason given is that the burrows are thereby opened. After a study of the microscopical appearances of active burrows, I have found that before any treatment these burrows are either already open at their entrances or have been scratched further open by the patient, or have had their roofs penetrated by emerging nymphs. The active ovigerous female usually lies in cuticle of normal appearance one or more millimetres ahead of the atrophic and friable portion of the burrow which would be removed by scrubbing. The mites are found to be killed by benzyl benzoate with the same speed and completeness whether a bath is given beforehand or not. I do not doubt that bathing assists the treatment of severe infections, crusted scabies, and rat scabies. The ova which may be recovered after benzyl benzoate therapy appear intact under the microscope, but when an attempt is made to hatch them by incubation they shrivel up and collapse, whereas ova removed before treatment develop normally. I have not found a second course of treatment to be necessary in any of the cases so far treated.

It will prove of great value to an Army in the field if further research reveals to what extent bathing and full disinfestation can safely be omitted from the treatment of scabies. Ablution and disinfestation facilities may thus be freed to deal with the more urgent problem of control of the louse. Such an advance can, however, only be made if the conclusions drawn from experience of the last war are re-examined by clinical observation and experiment, and are retained only so far as they are found to apply to the present day.—I am, etc.,

H. F. LUNN,
Captain, R A M C.

Operations and Workmen's Compensation

SIR,—The letter of Dr. Hermann Levy (July 18, p. 82) raises matters of great importance in regard to Workmen's Compensation; but there are others.

No one with any knowledge of the facts would deny the correctness of the observations made by Dr. W. A. Brend and quoted in Dr. Levy's letter. It would appear desirable that all cases coming within the Workmen's Compensation Act should be referred to a neutral body for decision. I suggest that the Ministry of Pensions is admirably suited to perform this work, as it has a highly trained medical personnel whose most important function is that of assessment of disability and disablement.—I am, etc.,

Tunbridge Wells. W. O. MOORE EDE.

Use of the Term "Orthopaedic"

SIR,—It would be a help to those wishing to arrive at an unprejudiced opinion on this matter if Brigadier Max Page would supplement his letter (July 18, p. 79) by giving the reasons for recanting the views expressed in his presidential address to the Section of Orthopaedics of the Royal Society of Medicine[1] in 1935, in which he stated: "The term

---

[1] Page, C. Max, *Proc. roy. Soc. Med.*, 1935, **29**, 63.

'orthopaedic surgeon' is now so well established in this country that the title is not likely to be displaced, although the later development of our specialty has marred its aptness. . . . The limited application of 'the term, which may be translated 'the correction of deformities in children,' was certainly lost when early in the nineteenth century the orthopaedic surgeon commenced to treat the adult, and the field of the specialty has widened ever since. Indeed, since the last war orthopaedics has so expanded that it may now properly be considered as that section of general surgery which deals with any disorder of the locomotor apparatus."

The aspiration of most orthopaedic surgeons would perhaps be best expressed by the exhortation of Sir Robert Jones[2] in a presidential address to the British Orthopaedic Association: "We should be known not by the label which is attached to us, which in many ways is unfortunate, but by the excellence of our work."—I am, etc.,

H. JACKSON BURROWS.

Maternity Service of the Future

SIR,—We submit below a memorandum on the improvement of the maternity services of the country, based on the statement made by Dr. Everett on our behalf at the meeting of the Section of Obstetrics of the Royal Society of Medicine on May 15.

The trend of what may be termed "official opinion" seems to be towards establishing a comprehensive institutional scheme for maternity service for the whole country, based on the rapid rise in institutional confinements during recent years. We recognize that in industrial and crowded urban districts institutional planning for the great majority is inevitable; but we wish to emphasize that over the greater part of the country—suburban, semi-rural, and rural—the ideal scheme will be based on the principle that many confinements will still take place in the home, partly because of the insufficiency of maternity beds, especially for private cases.

Such a scheme must be regional, and will entail the following: (A) A first line or periphery consisting of general practitioners and midwives. (B) Local hospitals with local consultants. (C) Central organizing consultants for each region.

As regards (A), the first line, we consider the general practitioner is essential for two reasons: (1) The personal relationship between doctor and patient. The majority of women planning for confinement ask that they shall be attended by their own doctor. Their confidence in the family doctor, with the doctor's knowledge of the patient's physical and mental make-up, is of inestimable value in the conduct of a maternity case. (2) The number of medical officers required to staff an efficient maternity service would render the exclusion of the general practitioner a practical impossibility. Not every practitioner wishes, or is necessarily competent, to practise midwifery. It is suggested that a list would be drawn up in each area, inclusion in which would imply willingness to serve, special training and/or experience, and an undertaking to attend postgraduate courses. The midwives would be highly trained responsible nurses, also with opportunity for refresher training. All patients treated at home must give the name of one of the doctors on the list for S O S service.

(B) The local hospitals and consultants would be established in suitable towns and country districts of the region. Adequate accommodation must be provided as regards number of beds (including private wards), equipment, and ancillary services (*x*-ray facilities, pathological laboratories, etc.). They would be available for all cases of difficulty or abnormality, as well as for mothers who prefer to be admitted for confinement. Central hospitals are unnecessary and disadvantageous because of the difficulties and dangers of transporting emergency cases over long distances, and the disinclination of patients to be removed to hospitals outside their own districts. The local consultants should form a most important part of the service, and their qualifications and selection should be very carefully considered. They should have had at least ten years' postgraduate experience of obstetrical practice. They should have had some experience of general practice, which would give understanding of the outlook and difficulties of the general practitioner, and they should preferably hold some higher degree in obstetrics. They should be chosen by the central consultant of the region, in consultation with the local practitioners of the service, in order to retain the confidence of the latter, without which their work would be gravely handicapped.

Ante-natal Care.—Ideally this should be the responsibility of the doctor who is to deliver the case, and it is unfortunate and manifestly wrong that at present much of this important work is in the hands of whole-time clinic medical officers, who never deliver a case. Doctors on the practising list should do their own ante-natal work. Midwives' patients should attend clinics under the local consultant, who would report and consult with the patient's doctor in every case of abnormality.

(C) The central consultant of the region should be an obstetric specialist of repute, and should be wholly responsible for the organization of the service in the area under his control. He should always be mobile and readily available to visit local hospitals in consultation or emergency.

We hope that when a comprehensive scheme is adopted for the maternity services of the country the general practitioner's point of view will be considered on the lines of the scheme here suggested.—We are, etc.,

G. WINN EVERETT.
EDWARD A. WILSON.
R. C. B. RAMSAY.
STEPHEN A. SCORER.

Bushey Heath, Herts.

Declining Population

SIR,—In one sentence Dr. Margaret Hadley Jackson (July 11, p. 55) vigorously denies that contraception is a cause of the decline in the birth rate, and in the very next she frankly admits that many persons are shying away from parenthood for a variety of reasons. And how? By the use of quinine and mercury and other noxious ingredients with or without or inside rubber products, which injure, often-times permanently, one of the most delicate and selective cell sites in the body—namely, the arbor vitae of the cervix. Is it to be wondered at that those who do routine gynaecological O.P.s or conduct sterility clinics in large teaching centres have found during the last ten years that more than 50% of patients with primary sterility have used contraceptive means or gadgets supplied to them by so-called welfare clinics; and that many a bride and young mother has a "strawberry" erosion indicative of endocervicitis, which it will take months of anxiety and care to treat, and even then with no security of prognosis? Nine years ago Séguy and Vimeux in Paris demonstrated that the penetrability of the cervical mucus plug, which is normally ever there, is in inverse ratio to the number of leucocytes present; in other words, the clearer and more transparent the glairy fluid, the more certain the chances of conception. It is this mucus plug, with the cells and glands that make it, that chemical contraceptives injure and alter.

In the early 'thirties Germany and Italy, closely followed by France, forbade by law the sale of contraceptives except in attested cases, and simultaneously they closed down the vested interests concerned, not merely for reasons of cannon fodder, nor for arguments of *Lebensraum,* but because their Registrars-General, like our own, viewed with dismay the fast-falling birth rates, well recognizing, as the Russians since have, that unchecked and indiscriminate birth control spelled not only race suicide but economic ruin; for had not Darwin and, later, Oswald Spengler testified that without numbers there can be no selection and no racial advance, and that decreasing fertility and increasing eugenism tended not only to the non-production of genius but also to the non-production of pioneers and leaders of men?

No one finds fault with spaced births after the first child. It is the necessity for the first child at an early date and at an early parental age that is imperative. Of course it is impossible to suppress birth control; but surely its principles should not be relaxed to-day, or its methods be injurious and/or unbridled, even before, as well as just after, matrimony. What is still more urgently necessary is, that the State should remove those obstacles and deterrents to parenthood that stifle instinct—the fear of poverty, the fear of physical breakdown, the fear of social decadence through lack of good educational facilities, the fear of failure or stoppage in a career. Only remission of taxation, housing relief, family endowment, and physical assistance schemes can lessen the risk of the childless, or one-child, family to itself and the State.

---

[2] Jones, Sir Robert. *J. Bone Jt. Surg.,* 1926, 8, 247.

There seems little doubt that Dr. Jackson is correct in assuming that the condition of subfertility is on the increase and to-day more frequently encountered. Among the multiple factors responsible I suggest that the present generation of young people are paying the price of ante-natal and post-natal avitaminosis in their parents during and after the last war; for there can be little question that the prevention of sterility begins *in utero* and continues through the periods of the first and second dentitions to the all-important time of puberty, when the greatest strain falls upon development and most particularly upon the generative system of both sexes, a time when every school doctor and home doctor should ever bear in mind that most wise axiom of Gowland Hopkins: "The vitamins are to the endocrines what the endocrines are to the economy."—I am, etc.,

London, W. V. B. GREEN-ARMYTAGE.

Treatment of Hypertension

SIR,—The leading article on hypertension (July 4, p. 15) will have interested a wide circle of readers, and none more than those who, like myself, have been using in recent years detoxication methods in the treatment of high blood pressure.

Now that it has been scientifically established that high blood pressure can be produced by a toxic agent which forms in the kidney when its blood supply is cut off, there will be less reason for us to draw upon our imagination when we try to explain good results. In future, when a marked fall in pressure occurs after a few days' or weeks' treatment, shall we not be justified in claiming that this has occurred as a result of nullifying the action of that toxic agent by some method of detoxication which has been employed? Further, when symptoms we associate with the progressive stages of Bright's disease gradually disappear as treatment continues (an experience I have had on many occasions when using the permanganate method of detoxication that was introduced by Nott in a paper in the *Journal* of Dec. 26, 1925) need we be so greatly surprised by the remarkable results achieved?

Since we are now told that when only one renal artery in the experimental animal is clamped changes take place in the minute anatomy which are indistinguishable from those seen in Bright's disease, and that these changes are also found in the undamaged kidney, does this not suggest that the permanganate method has the power at times of neutralizing this self-same toxic agent when it is circulating in the blood? If this is so, have we not a scientific explanation for the remarkable results which Nott reported in the paper referred to above? As I am one of many who have used his treatment regularly for the past 17 years with great success, I believe I shall be expressing their opinions as well as my own when I ask if the time has not come to accord a little credit to one who has added something of very great value to our therapeutic knowledge?—I am, etc.,

London, W.1. GILBERT ORME.

Nurses in Hospital

SIR,—Dr. S. L. B. Wilks writes (July 18, p. 84) that "the brutality of matrons (and sometimes of sisters) to their nurses is notorious" and "needs no investigation," and goes on to state that "the remedy lies with hospital boards and medical officers." I submit that his statements and the general tone of his letter are unsupported by well-known and widely recognized facts, and that they constitute an unjustifiable and gross attack upon many who are the responsible leaders of a great profession, and contain also a libel on hospital boards and their medical officers.

I suggest that the need for Dr. Wilks to make an investigation is very great, and that if he will be at some pains to extend his knowledge of relevant facts he will find that the one hospital he knows well has its equals all over the country, and that matrons throughout the land are loyally and ungrudgingly caring for the welfare and interests of their nurses and probationers.—I am, etc.,

Inverness. T. C. MACKENZIE, M.D.

Obituary

H. S. BIRKETT, C.B., M.D., LL.D.

Many medical men in this country have already heard with much regret that Brigadier-General Henry Stanley Birkett, the eminent Canadian laryngologist, died on July 19 at Montreal, where he occupied the chair of laryngology and otology in McGill University for 37 years and was dean of the medical faculty for eight years. At four annual meetings of the British Medical Association he held office as vice-president of his section: 1897, Montreal; 1906, Toronto; 1930, Winnipeg; and 1932, Centenary Meeting in London.

Born on July 17, 1864, at Hamilton, Ontario, the son of William Birkett, merchant, Birkett came to this country for his early education at Chester. He returned to Canada for medical study at McGill, graduating M.D., C.M., and winning the Holmes gold medal in 1886. His long service to the Montreal General Hospital began as house-surgeon, and he was appointed laryngologist in 1891. At McGill University he was a demonstrator of anatomy for seven years, and became professor of laryngology and otology in 1895 and emeritus professor in 1931. His tenure of the post of dean of the medical faculty was interrupted by the last war, during which he gave outstanding military service. He organized and commanded for 3½ years No. 3 Canadian General Hospital (McGill) for service with the B.E.F. in France. He was then made consultant in oto-laryngology at Boulogne, and in 1918-19 Assistant Director-General of the Canadian Medical Services over-seas with the rank of brigadier-general. In these posts he made many lasting friendships with British medical officers, both regular and temporary. He was created C.B., Military Division, in 1917, and received the Colonial Officers' Auxiliary Decoration.

Birkett's standing in his own specialty may be judged from the offices he held at one time or another: President of the American Laryngological Association, of the American Otological Society, and of the American Laryngological, Rhinological, and Otological Society; Honorary President of the Clinical Congress of Laryngology, held in London in 1919; Semon lecturer, University of London, 1922; honorary member of the Scottish Otological and Laryngological Society, of the American Academy of Ophthalmology and Oto-laryngology, and of the Italian Society of Laryngology. He was consulting laryngologist and otologist to the Royal Victoria Hospital, Montreal, a governor of the Montreal General Hospital, and past-president of the Montreal Medico-Chirurgical Society, of which he had been general secretary. McGill University conferred upon him its LL.D. degree *honoris causa* in 1921. He wrote many papers on diseases of the throat and nose, contributed to Osler's *System of Medicine* and to Jackson and Coates's large textbook, and published his Semon lecture on the transatlantic development of rhino-laryngology.

W. K. ANDERSON, M.D., F.R.F.P.S.G.

By the death of Dr. William Kirkpatrick Anderson, which took place on June 27, Glasgow has lost one of its physicians specially known for his work in psychological medicine. He received his medical education in Glasgow University, graduating M.B., Ch.B. in 1902 and M.D. in 1926. He became a Fellow of the Royal Faculty of Physicians and Surgeons, Glasgow, in 1924. His professional training was continued a Dundee Royal Infirmary, and he then entered general medica practice in Glasgow, at the same time developing his inclinations towards psychological medicine. In 1914 he was appointed by the Corporation of Glasgow visiting physician and physician in psychological medicine to the Eastern District Hospital and to Stobhill Hospital. In 1923 he became lecturer in psychiatry in the Anderson College of Medicine, proving himself to be a popular teacher, gaining the confidence of those who appreciated his instruction. During and after the last war he had charge of the mental wards in Dykebar Military Hospital Renfrewshire. Dr. Anderson made frequent contributions to medical literature, some of which were: "Morphinomania" and "Gastric Infection secondary to Oral Sepsis and Systemic Disease," published in the *Practitioner*; and his chief work on

Malarial Psychoses and Neuroses, published in 1927, was generally accepted as a standard book of reference on the subject. He also published in the *Glasgow Medical Journal* a paper entitled "The Superior Mediastinum in its Clinical Aspects: with Special Reference to Signs of Aneurysm of the Transverse Aorta"—a record of 110 cases; and in conjunction with Drs. Horowitz and Palmer an account of a case of a fatal agranulocytosis after sulphapyridine therapy.

Dr. Anderson travelled frequently on the Continent, visiting German medical and psychological clinics in Dresden, Munich, Berlin, and Vienna, and some of the sanatoria in Switzerland. He was keenly interested in social work and was a generous contributor to various means of carrying on this activity. His literary interests were specially centred in biography, particularly that relating to American statesmen. His many professional friends will cherish happy remembrances of a man who had the gift of friendship, and one who maintained the highest traditions of his profession.

Dr. **GEORGE BECKETT BATTEN**, who died on July 9 at Dulwich, was one of the earliest workers in radiotherapy, for he began treatment of ringworm of the scalp by *x* rays in October, 1896. He was born in India, near Agra, on November 10, 1860, and was educated at Haileybury College, of which his grandfather had been the first Principal when the school was established under the aegis of the East India Company. He went up to Edinburgh University with a reputation for prowess in games, and having graduated M.B., C.M. in 1884, became house-surgeon at the Royal Infirmary; he proceeded M.D. in 1887. Entering a partnership in Dulwich he took a prominent part in local affairs and was one of the joint founders of the Peckham centre which, under the L.C.C., was known later as the Old Kent Road Clinic. Dr. Batten joined the B.M.A. 57 years ago, and had been chairman of the Norwood Division in 1914-15 and of the Camberwell Division 1920-3. During the last war he was surgeon in charge of the *x*-ray department of the Southwark Military Hospital, combining this work with that of honorary radiologist to the Children's Hospital, Sydenham. In 1918 he was president of the Roentgen Society, and in 1921 was one of the first to receive the D.M.R.E. of Cambridge. He was a past-president of the Electrotherapeutic Section of the Royal Society of Medicine, and one of the earliest Fellows of the Faculty of Radiologists. His daughter, Dr. Grace Batten, is a group radiologist in the L.C.C. medical service.

Dr. **GEORGE VIGERS WORTHINGTON**, who died suddenly at Llandrindod Wells on July 8, had a varied career before settling down to spa practice. The son of a doctor, he was born at Lowestoft on May 18, 1870, and from Marlborough College went up to Pembroke College, Cambridge, and thence to St. Bartholomew's Hospital, graduating M.A., M.B., B.Ch. in 1895. After serving as house-surgeon at Bart's he won the Brackenbury surgical scholarship, and then spent two years in India holding various appointments. During the South African War (in which he was awarded the Queen's medal and clasp) Dr. Worthington was second surgeon to the Princess Christian Hospital and later specialist plague M.O. for Cape Colony. In the last war he held a temporary commission in the R.A.M.C., as medical officer to the Red Cross and Auxiliary Military Hospitals at Llandrindod Wells and consulting medical officer to the Red Cross Hospital at Knighton. He was the author of several papers on spa treatment of arteriosclerosis and rheumatoid arthritis, and wrote a little book on the climate and waters of Llandrindod Wells. He joined the B.M.A. in 1897 and served on the Spa Practitioners' Group Committee from 1934 to the time of his death.

Dr. **RICHARD OGILVIE GIRDWOOD**, pathologist to the Southern Group of Hospitals, Liverpool, has died at the house of his mother in Aberdeen. He was born on June 16, 1896, and graduated M.B., Ch.B. of the University of Aberdeen in 1923, after which he served for a time as assistant in the pathological department of that university, then as assistant city pathologist and bacteriologist at the Bradford Municipal Laboratories, and as senior assistant pathologist to the Royal Sussex County Hospital, Brighton. Before taking up his appointment at Liverpool in 1937, Dr. Girdwood had worked on insulin at St. Thomas's Hospital and had published a number of papers on pathological subjects in the *Journal of Pathology and Bacteriology*. He joined the B.M.A. in 1924.

Alderman **JAMES HENRY CHESSYRE DALTON**, M.D., a veteran worker for the public health, died on July 13 at his home in Cambridge. He was born in Manchester on April 15, 1861, and from Marlborough College went up to Trinity College, Cambridge, in 1880. He was placed 12th Wrangler in the Mathematical Tripos of 1884 and went on to study medicine in London at St. Mary's Hospital, qualifying in 1889. After taking the M.D. degree and the D.P.H. in 1893 he returned to Cambridge to devote himself largely to problems allied to public health. He was elected a guardian in 1898 and a town councillor soon afterwards, and for many years served as chairman of the Public Health Committee. In 1903 he was Mayor of Cambridge and in the following year was appointed a justice of the peace. In 1907 he was elected to the County Council and became a county alderman in 1928. When the Education Act came into force he accepted chairmanship of the Borough Maternity and Child Welfare Committee. Throughout all his years of public service Dr. Dalton was indefatigable in his efforts to raise the health standards of both the county and the borough, and he worked in close touch with the officers concerned. As chairman of the Tuberculosis Committee his work was invaluable. Dr. Dalton joined the B.M.A. in 1891 and represented the Cambridge Division at the Annual Meeting in Belfast in 1909. One of his sons is Dr. C. H. C. Dalton of Ipswich.

Dr. **JAMES ERNEST SCANLAN** died at Middlesbrough on July 15 with tragic suddenness, aged 51. The only son of the late Dr. A. E. Scanlan of Middlesbrough, he was educated at Epsom College and at St. Mary's Hospital, and after qualification served from 1916 till 1918 as surgeon lieutenant R.N.V.R. on Atlantic Patrol. At the conclusion of the war he joined his father in practice and ultimately succeeded him. For twelve years (1919-30) Dr. Scanlan was assistant surgeon to the North Riding Infirmary, and only resigned when he found that the increasing calls of a large general practice made it impossible to devote the necessary time to his hospital duties. He was a keen Freemason, a Past-Master of the Ferrum Lodge and a Past-Principal of the Ferrum Royal Arch Chapter. Only two months ago he received the honour of P.P.G.H. He had been a member of the B.M.A. for many years. Dr. Scanlan is survived by his wife and two daughters. He will be greatly missed by a large circle of personal and professional friends.—G. H. L.

Universities and Colleges

UNIVERSITY OF LONDON

LONDON HOSPITAL MEDICAL COLLEGE

The following Entrance Scholarships have been awarded for 1942-3: Price Scholarship in Science (value £100)—K. L. Cleminson. Epsom Scholarship (free medical education)—D. R. Reid. Price University Scholarship (open to students of Oxford and Cambridge; value, £100)—J. T. Wright (Worcester College, Oxford). Open University scholarship: (*a*) £100—J. C. Sloper, Corpus Christi College, Cambridge; (*b*) £100—A. G. Beckett, Merton College, Oxford.

GUY'S HOSPITAL MEDICAL SCHOOL

The following awards have been made for 1942:

Entrance Scholarships in Arts.—Scholarship, value £100, C. J. Earl. Exhibitions, value £50, P. A. Shave and C. H. Neaves. War Memorial Scholarship in Science, value £200, E. L. W. Leiser. Entrance Scholarship in Science, value £100, J. D. Oriel.

ROYAL CANCER HOSPITAL (FREE)

The following candidates have been approved at the examination indicated:

ACADEMIC POSTGRADUATE DIPLOMA IN MEDICAL RADIOLOGY.—L. S. Carstairs, R. C. M. Hadden, G. M. Ross, *D. W. Seth-Smith.

UNIVERSITY OF SHEFFIELD

At its last meeting the University Council received the resignation of Dr. M. S. Spink of his posts of assistant bacteriologist and demonstrator and temporary lecturer in bacteriology. The Council accepted the resignation with regret and accorded its thanks to Dr. Spink for his services to the university.

UNIVERSITY OF EDINBURGH

A graduation ceremony was held on July 15, when the following degrees and diplomas were conferred:

M.D.—[2]J. N. Hay, [2]W. K. Henderson, [4]Major D. M'Intosh, R.A.M.C., D.S.O., [4]Lieut. A. C. Mackenzie, I.M.S., [1]Major-Gen. J. A. Manifold, A.M.S., [14]Lieut. J. M'D. Simpson, R.A.M.C., [2]J. Thomson.

M.B., CH.B.—Grace B. Aitken, A. F. Alexander, Harriet J. M. Arnott, Mary A. Ashton, G. M. Baird, [3]A. H. Banton, R. C. Bignold, R. E. Bosanquet, [3]I. D. B. Bottomley, H. M. Bradmore, A. W. Branwood, Agnes A. Brash, J. Brims, Margaret E. Browne, Elizabeth S. Brydone, W. H. Burnett, Violet S. Burns (*née* Dow), Catherine C. Burt, J. D. Caldwell, Yun-sun Chang, G. R. Clark, M. J. Colbourne, J. O. Craig, Jessie A. R. Cripps, W. L. Cummings, R. Cutts, J. T. Donaldson, Rose I. L. Donaldson, [3]J. P. Duguid, T. B. Dunn, J. R. Fountain, M. S. Fraser, W. J. Fraser, [3]R. M'K. Fulton, R. P. Gillespie, J. G. Gilmour, N. J. Graham, D. C. Haig, J. D. Halford, Barbara Hall, C. W. Hamilton, W. R. Hatswell, J. Haworth, J. A. Howell, J. C. Inglis, G. D. Jack, E. L. Jacobs, G. M. Jones, I. S.

Kirkland, J. E. Laing, J. M. Large, A. R Laurence, K MacK. Leitch, [3]L. G. Leitch, W. S. Locke, [3]R T. S Louttit, C. S. R. Lowdon, A. A. C. MacArthur, D. G M'Cann, A. J. A. M'Cormick, A. B M'Culloch, J. A. M'Ghie, D. A. Maciver, J R. Mackenzie, Elizabeth M'Kenzie-Newton, Joan E. W. Mackie, J. S M'Kinnell, A. T. MacKnight, D. G. Maclean, A M'Queen, K. A. M'Rae, A F J. Maloney, F. D. Martinson, D S Matthews, I D. Maxwell, G. O. Mayne, A L. Meikle, J. L. Merson, Violet F. Michie, S L Mitra, Enid M Monson, E V. B. Morton, E N Moyes, Alexandrina K Muir, Edith R Munro, D J G. Naudé, M. J. D Noble, J. Philip, D. Ll Richwhite, A. C. Ritchie, Rosemary R. M Robinson, S. H. Roe, J. R Rook, Grace Ross, T. M. Rowatt, Diana T Rushforth, Sheina B. Scott, J A Simpson, W. P Small, R H N. Smith, S. P Smith, [3]J D. T. Steele, Joan E Stewart, I H Stokoe, J N Swanson, J. H Taylor, W. N. Taylor, Mair E M Thomas, B A. Thompson, Anne M. Toms (*née* Brown), A F. Torrie, Katherine E C. Traquair (*née* Forbes), A N Val Davies, D R Wallace, J A K. Wallace, Marion E Welsh, L. Willson, T. M'S. Wilson, W. A. Wilson, Margaret P Yeoman, J. Young

D P H—[4]Marguerite E. M Day, Jessie M L. Goodbrand, J N. Hay, [4]B. T. Jones, [4]Ethel J Kay, [4]Margaret S. B Langton, [4]Beryl J Lawrence, E. J. M Shearer, [4]Doreen M Waddington.

DIPLOMA IN TROPICAL MEDICINE AND HYGIENE.—F O Adewole, W. A M Akiyemi, L G. Bruce, J. Crabb, W. E. Lawes, C H H B Sparrow

The following prizes were presented:

Ettles Scholarship and Leslie Medal, Beaney Prize in Anatomy and Surgery, Royal Victoria Hospital Tuberculosis Trust Medal, and Annandale Medal in Clinical Surgery: R T. S Louttit. *Scottish Association for Medical Education of Women Prize:* Grace Ross. *Mouat Scholarship in the Practice of Physic:* R. T S Louttit, prox acc., I. D B Bottomley *Buchanan Scholarship in Midwifery and Gynaecology, Wightman Prize in Clinical Medicine, Sir Robert Jones Prize in Orthopaedic Surgery, and Stark Scholarship in Clinical Medicine:* A. H Banton. *James Scott Scholarship in Midwifery and Gynaecology:* A. J. A. M'Cormick. *Dorothy Gilfillan Memorial Prize* Sheina B Scott. *Keith Memorial Prize in Systematic Surgery:* I D B. Bottomley *Murdoch Brown Medal in Clinical Medicine:* M J Colbourne *Pattison Prize in Clinical Surgery.* W P Small *Syme Surgical Fellowship:* A W Wilkinson *Vans Dunlop Scholarship in Materia Medica and Medicine:* Sheila P V. Sherlock. *Gunning Victoria Jubilee Prize in Botany.* Elizabeth G. Gray *Gunning Victoria Jubilee Prize in Forensic Medicine.* L. F Brown. *Thomson Memorial Medal in Child Life and Health:* R. M MacDonald *Lewis Cameron Undergraduate Prize in Bacteriology:* R J. M M'Cormack, R. F Robertson, and P. R Walbaum (equal) *Anderson Henry Prize in Botany.* J. M'A Todd. *Colonel Thomas Biggam Memorial Medal and Prize in Pathology:* R F Robertson *Maclagan Prize in Forensic Medicine* H T. G Strawbridge *Cunningham Memorial Medal and Prize in Anatomy* I S. R. Sinclair. *Whiteside Bruce Bursary* Rosemary W Lawrence. *Vans Dunlop Prize in Botany and Zoology:* Barbara E. Clayton

ROYAL COLLEGE OF PHYSICIANS OF EDINBURGH

At a quarterly meeting of the College, held on July 21, with the President, Dr. Charles McNeil, in the chair, Dr. William George Clark (Edinburgh) was elected a Fellow of the College.

Medical Notes in Parliament

Emergency Hospital Scheme

On July 13 Mr. DAVID ADAMS asked the Minister of Health whether he was aware of the cumbersome character of the administration of the Emergency Hospital Scheme, necessitating a multiplicity of forms and returns; that the Ministry had recently instituted a complicated record form for the medical notes of patients admitted to chest centres; that a recent draft weekly return for wartime day nurseries had to be submitted in triplicate asking for information under 27 different heads; and whether he would cut down the size and number of these forms. Miss HORSBRUGH said that it was the constant effort of the Emergency Hospital Scheme to restrict its forms and returns to the minimum necessary for conducting so considerable a service effectively, and for meeting Service requirements, keeping relatives informed, and ensuring proper treatment of patients. The form E.M.S.105 was a simple form used, with carbon copies, for Service and police cases and civilian casualties. It was the main means of recording the admission and movement of such patients, of informing relatives and Service authorities, and of enabling proper allocation to special treatment to be followed up. The form for certain chest cases applied only to a small number of specialist cases, enabled the medical case notes to be kept on more uniform lines, and so helped in continuity of treatment when patients were moved, as well as enabling specialist treatment methods to be observed and improved. She was making inquiries from the regional offices about the return for wartime nurseries, as no such return was required centrally.

Tuberculosis Treatment in Wales

Mr. ERNEST BROWN on July 14 met a deputation from the Welsh Parliamentary Party to discuss tuberculosis treatment in Wales. The deputation included Sir Henry Morris-Jones. The Minister said that the Welsh Board of Health had had consultations with the Welsh National Memorial Association. The latter's lengthening list of people awaiting treatment was largely due to an increase in civilian cases, probably resulting from wartime conditions; the discharge of unfit men from the Forces; and inability to use all available beds owing to lack of staff—in particular, domestic staff. Moreover, the trend was for the period of treatment in hospital to lengthen, resulting in a slower turnover of cases. The present waiting list numbered just over 500; of whom about 100 were Service or ex-Service men. The number of beds available in the Association's own institutions was 1,969, including 160 beds rented to the Association from the emergency hospital provision. Of these 1,969 beds, 128 were out of commission owing to shortage of nursing and, particularly, domestic staff. The employment of non-resident and part-time domestic staff had been widely adopted but had not been able to meet requirements. The Ministry of Labour had recently instructed its Regional Controllers to give preference to filling vacancies for domestic workers at hospitals, with special emphasis on sanatoria. It might be possible to provide more beds from the Emergency Hospital Scheme, and some help might be given at the new 600-bed hospital shortly to be opened near Swansea.

Hospital Survey in Lancashire and Cheshire

On July 21 Mr. ERNEST BROWN informed Major Owen that the terms of reference to the officers whom he had appointed to survey the hospital services in the North-West were: "To survey the hospitals (other than mental hospitals and mental deficiency institutions) in the geographical counties of Lancashire and Cheshire, and in North Wales and other neighbouring areas which look to those counties for hospital treatment; and having regard to the information thus obtained, and to the general principles of post-war hospital policy laid down by the Minister of Health in the House of Commons on Oct. 9, 1941, to advise the Minister what areas would appropriately be served by a hospital system centred on the teaching hospitals of Liverpool and Manchester, and what modifications or extensions of the existing hospital facilities would be necessary or desirable to give effect to that policy." The terms of reference made no express mention of Bangor.

Last-war Service and Gazette Rank

On July 21 Sir ALFRED KNOX asked the Secretary of State for War whether it was his intention that medical men who served in the last war in the rank of lieutenant or captain, R.A.M.C., should now be called up at the age of 41 to 46 years and posted to serve under youths of 25 to 30 years of age, who only received their medical degrees a few months ago. Sir JAMES GRIGG replied: Medical men called up for service who held commissions in the R.A.M.C. for a year in the last war are gazetted captain from the date of joining. Few R.A.M.C. officers under 30 are commanding units, and these are in all cases Field Force units with active duties, to which it is not intended to post the 41- to 46-year-old officers.

Maternity Accommodation in Glasgow.—On July 14 Mr. JOHNSTON, replying to Mrs Hardie, said he had seen the report of the Medical Officer of Health for Glasgow that the demand for indoor accommodation for confinements was increasing and was very difficult to meet The aim of the Government's hospital policy was to secure that hospital treatment should be available to every person in need of it, and that included adequate provision for maternity cases. In the meantime, expectant mothers in Glasgow might be admitted to emergency homes outside the city set up under the Government evacuation scheme, in which there was at present vacant accommodation.

Alien Dentists—Miss HORSBRUGH, on July 14, informed Mr Harvey that the Minister of Health was fully alive to the need for making all possible use of dental man-power available in the country, and the question of facilitating the employment of alien dentists with registrable qualifications had recently been discussed by his Department with the Home Office, the Board of Education, and representatives of the dental profession. The school medical service probably offered the best scope for the employment of these dentists, and a memorandum was issued to local education authorities on this subject last April by the Board of Education Permission to practise could not be given to dentists not possessing registrable qualifications without admitting a standard lower than that required of British applicants. This course had obvious objections.

Tuberculosis in Glasgow School Children.—On July 14 Mrs. HARDIE asked the Secretary of State for Scotland if, in view of the increase in the number of cases of suspected tuberculosis among children examined on entrance to Glasgow schools, he would have an investigation made into the quality of the milk supplied in the city Mr. JOHNSTON said he had no reason to believe that the milk supplies to Glasgow were the cause of any part of the increase in suspected tuberculosis. The cases in question were of suspected pulmonary tuberculosis, which was not generally due to bovine infection conveyed by milk.

Notes in Brief

On March 31 last there were 1,507 persons in England and 400 in Wales who had been on local authority waiting lists for institutional treatment for tuberculosis for upwards of 10 days. In Scotland at that date 652 persons had been awaiting admission for more than four days.

The Services

Capt. (Temp. Major) G. F. Edwards, R.A.M.C., has been appointed an M.B.E. (Military Division) in recognition of gallant and distinguished services at Malta.

CASUALTIES IN THE MEDICAL SERVICES

Lieut. Eric Mace Foster, R.A.M.C., the only son of Mr. and Mrs. S. M. Foster of West Bromwich, was accidentally drowned on March 26 while serving with the Middle East Forces. He was born on June 26, 1918, and was educated at the University of Birmingham, where he graduated M.B., Ch.B. in 1940. After holding hospital posts he entered the R.A.M.C. as temp. lieut. in Aug., 1941, and was posted to the Middle East a few months later. He was a member of the B.M.A.

Missing.—Lieut.-Col. G. F. A. Condon, I.M.S., Capt. J. V. Schofield, R.A.M.C.

Wounded.—Brigadier R. R. G. Atkins, M.C., Temp. Surg. Lieut. G. P. Fahrni, R.C.N.V.R., War Subs. Capt. W. B. McKenna, R.A.M.C.

DEATHS IN THE SERVICES

Major-General Thomas George Ferguson Paterson, C.B., D.S.O., I.M.S. (ret.), late of Aldeburgh, Suffolk, died in a London nursing home on July 7, aged 65. He was born on Dec. 6, 1876, and was educated at Trinity College, Dublin, where he graduated B.A. in 1899 and M.B., Ch.B., B.A.O. in 1901. He entered the I.M.S. as lieut. in 1902, became capt. in 1905, major in 1913, brevet lieut.-col. in 1919, lieut.-col. in 1921, brevet col. in 1928, col. in 1930, and major-gen. in 1932, retiring in 1935. He served throughout the war of 1914-18 in Iraq and Egypt, was wounded at Sahil, and was twice mentioned in dispatches and received the D.S.O. in 1917. He was appointed an Honorary Physician to the King in 1928 and received the C.B. in 1935. During his service in India he held the post of Deputy Director of Medical Services, Northern Command. He had been a member of the B.M.A. for 32 years.

EPIDEMIOLOGICAL NOTES

Discussion of Table

A decline in the incidence of infectious disease was recorded in England and Wales during the week. Diphtheria was the only disease with an increased incidence, there being 40 more cases than in the preceding week. The differences between the totals for the counties for the past two weeks were generally very small. The largest variation shown by scarlet fever was in London, where 25 fewer cases were recorded last week than in the previous one. The greatest variations in the returns for whooping-cough were a decrease of 50 cases in Kent and an increase of 28 in Staffordshire. An outbreak of diphtheria involving 44 persons in Kent, Romney Marsh R.D., was the outstanding feature of the returns for this disease. These were the first cases reported from this area during the present year.

The notifications of measles were 220 fewer than in the preceding week, when the very large increase of 1,206 was reported. The counties with the largest decreases in incidence were Middlesex, London, Surrey, and Essex, where 151, 78, 72, and 65 fewer cases were recorded. The largest increases were those of Nottinghamshire 116, Hampshire 62, Kent 60, and Staffordshire 51.

The incidence of dysentery decreased by 87, due to the decline in the outbreak in Cumberland, Penrith U.D., where 31 fresh cases were reported, compared with 100 in the preceding week. New outbreaks occurred during the week in Buckinghamshire, Newport Pagnell R.D. 16 cases, and Shropshire, Ellesmere R.D. 7 cases.

The chief features of the returns for Scotland were an increase in the notifications of scarlet fever and a decrease in the number of cases of diphtheria. The rise in the incidence of scarlet fever was due to an outbreak in Paisley, where 56 cases were reported, compared with 4 the previous week. The incidence of measles, which fell by 273 and 358 cases in the preceding two weeks, showed a further small decline of 18.

Returns for the Week Ending July 18

The notifications of infectious diseases during the week in England and Wales included: scarlet fever, 1,558, whooping-cough 1,295, diphtheria 692, measles 7,050, pneumonia 516, cerebrospinal fever 83, acute poliomyelitis 16, dysentery 198, paratyphoid 6, typhoid 5.

No. 27

INFECTIOUS DISEASES AND VITAL STATISTICS

We print below a summary of Infectious Diseases and Vital Statistics in the British Isles during the week ended July 11.

Figures of Principal Notifiable Diseases for the week and those for the corresponding week last year, for: (a) England and Wales (London included). (b) London (administrative county). (c) Scotland. (d) Eire. (e) Northern Ireland.

Figures of Births and Deaths, and of Deaths recorded under each infectious disease, are for: (a) The 126 great towns in England and Wales (including London). (b) London (administrative county). (c) The 16 principal towns in Scotland (d) The 13 principal towns in Eire. (e) The 10 principal towns in Northern Ireland.

A dash — denotes no cases; a blank space denotes disease not-notifiable or no return available.

Disease	1942					1941 (Corresponding Week)

† Owing to evacuation schemes and other movements of population, birth and death rates for Northern Ireland are no longer available.

Medical News

The seventeenth Congress of the French Medical Association of North America will be held at the Hôtel Mont-Royal, Montreal, on Sept. 14 to 17.

The second Latin-American Congress of Plastic Surgery will be held at Buenos Aires in October. The exact date will be announced later.

The Minister of Health, opening a new six-day residential nursery in Leeds last week, said that there were now 700 wartime nurseries in Britain, and another 700 were under construction.

His Excellency the Soviet Ambassador has made a donation of £100 to the work of the Anglo-Soviet Medical Council.

At the annual general meeting of the Central Council for Health Education Dr. Charles Hill was elected chairman in succession to Dr. W. Allen Daley, who, with Sir Walter Langdon-Brown, was elected vice-president. Dr. Maitland Radford succeeds Dr. Hill as vice-chairman, and Mr. Henry Lesser has been re-elected honorary treasurer.

The many friends in this country of Prof. A. Castiglioni, formerly professor of the history of medicine at Padua, will be glad to know that he is giving a series of weekly lectures on medical history at the Yale University School of Medicine.

Beginning with its issue of May 9 the *Journal of the American Medical Association* is devoting a section each week, entitled "Medicine and the War," containing official notices by the Committee on Medical Preparedness of the A.M.A., announcements by the Surgeon-Generals of the Army, Navy, and Public Health Services, and other Government agencies dealing with medicine and the war.

For some time now school medical officers have tended to reduce the period during which a child contact of a case of infectious disease should be kept away from school; in some instances, even, the contact has continued at school. The Ministry of Health and the Board of Education have issued a joint statement on this matter, bringing the official memorandum (last revised in 1927) more into line with medical opinion. Copies of the memorandum can be obtained from H.M. Stationery Office, price 1d.

Letters, Notes, and Answers

All communications in regard to editorial business should be addressed to THE EDITOR, BRITISH MEDICAL JOURNAL, B.M.A. HOUSE, TAVISTOCK SQUARE, LONDON, W.C.1.

ORIGINAL ARTICLES AND LETTERS forwarded for publication are understood to be offered to the *British Medical Journal* alone unless the contrary be stated.

Authors desiring REPRINTS should communicate with the Secretary of the Journal Board, B.M.A. House, Tavistock Square, W.C.1, on receipt of proofs. Authors over-seas should indicate on MSS. if reprints are required, as proofs are not sent abroad.

ADVERTISEMENTS should be addressed to the Advertisement Manager (hours 9 a.m. to 5 p.m.). Orders for copies of the *Journal* and subscriptions should be sent to the Secretary.

TELEPHONE No.—B.M.A. and *B.M.J.*: EUSTON 2111.

TELEGRAPHIC ADDRESSES.—EDITOR, *Aitiology Westcent, London*; SECRETARY, *Medisecra Westcent, London*.

B.M.A. SCOTTISH OFFICE: 7, Drumsheugh Gardens, Edinburgh.

QUERIES AND ANSWERS

Artificial Respiration in Phosgene Poisoning

Dr. J. L. BARFORD (Redhill, Surrey) writes: I recently heard it advocated by a medical A.R.P. instructor that as a last resort artificial respiration—presumably by Schafer's method—should be tried in case of phosgene poisoning when oxygen, CO_2, etc., were unavailable. It was pointed out that the patient, having stopped breathing as a result of flooding of the lungs with exudate, would undoubtedly die if nothing was done, and that such an extreme measure was advisable in the hope, presumably, that the movements, rhythm, and position would help to drain the lungs and possibly to stimulate the respiratory centre. As artificial respiration in these cases is very definitely vetoed in the manuals and charts, I should be glad to have any further expert advice or opinion. Secondly, in a book review in your columns recently the author advocated direct transpiration in the treatment of blast injury of the lungs. Is there any evidence in other literature of the usefulness of this procedure?

Persistent Psoriasis

Dr. C. W. PATTERSON (Golcar, near Huddersfield) writes: With regard to the query of S. C. M. concerning psoriasis (May 9, p. 600) the following may be of interest. (1) At a recent medical board a man was seen with typical psoriasis, who said that the eruption occurred every 7 years, lasted a few weeks, and then cleared up. Periodicity in disease is often traceable to some nervous origin. (2) About 5 years ago I was consulted by a girl of 17 for psoriasis of trunk and limbs. After treating her unsuccessfully I sent her to the out-patient department of the local hospital. About 2 years later I visited a member of the family, and on one occasion asked the mother how the daughter with psoriasis had progressed. With apparent reserve the mother replied that the girl was completely cured. When asked what remedy had been successful the mother said that after attending the hospital for a year there was no improvement, but that an elderly pedlar had called one day, and, seeing the girl's arms, had volunteered to cure her. When pressed for information the rather embarrassed mother informed me that the "cure" was to dab her own urine upon the eruption when retiring at night. Relief and cure were rapid. When I saw the patient subsequently and the "cure" was discussed, I asked, "But didn't it smell?" The rather elegant young woman replied, "Well, naturally, but I washed it off next morning." Was this cure by suggestion? I might add that in the course of 23 years' practice I have encountered two patients who have confessed to drinking their own urine as a cure for "rheumatism." One would think that if ever cure by suggestion were likely to succeed this is, *par excellence*, the example.

A Case of Neurosis

"X" writes: The patient described by J. W. M. (June 27, p. 808) would probably be greatly assisted by a spray of 2% percaine. He could use this with safety up to a maximum of six or seven times a day, and it is highly probable that within a few days his habit of vomiting would be broken. I have had an almost exactly similar case and this line of treatment was highly successful.

LETTERS, NOTES, ETC.

Nomenclature of Night-blindness

Dr. J. PRICE WILLIAMS (Ambleside) writes: In his interesting article on night-vision tests (June 27, p. 800) Mr. Francis Preston makes a welcome and praiseworthy effort to supply a long-felt want by finding a new word to replace "hemeralopia" and "nyctalopia," a word which will express itself and leave little or no room for confusion. He suggests "nyctamauria" or "nyctamauroma." I don't object to the former, but must protest against the latter on a ground which he himself indicates. The termination "oma" is common enough, but it is used invariably to express something concrete or objective (see his little list), whereas blindness, whether by day or night, is mainly, if not entirely, abstract or subjective. It is a condition or state, and the termination we usually employ to express that is "osis" and not "oma"—e.g., pediculosis, diverticulosis, and (oh!) tuberculosis. Perhaps "nyctamaurosis" would be better than "nyctamauria" in spite of its extra syllable and lack of strict accuracy. We already have "amaurosis" to express one form of blindness, and I think a good many of us regard it as the equivalent of blindness in general. Hence the word would tell its own tale and would be consistent with the other "oses." Even if we feel bound to invent "hemeramaurosis" to balance it there would be no room for confusion.

MEDICINE 100 YEARS AGO

Extract from letter by J. F. H. R. W. in the *Provincial Medical Journal* for July 30, 1842, headed "Parochial Medical Relief":

"Gentlemen,—Should the following observations be deemed of sufficient importance to obtain insertion in your very useful Journal, I shall feel both flattered and obliged. In the present age of improvement, I venture to offer some suggestions relative to the medical relief of the poorer classes. It has long been my opinion that parish patients would feel much more satisfied, and have less aversion to the existing poor laws, were they permitted, when ill, the privilege of choosing their own medical attendant. I have frequently heard them exclaim, 'We are not even allowed the surgeon we like best, but are obliged to be attended by a man of whom we know nothing, or by one we cannot trust.' I need scarcely appeal to you, as members of the profession, for confirmation of the fact how, in many instances, faith in the skill of the professional person tends to alleviate the sufferings of the patient, and acts in some measure as a remedy to the disease itself. The privations to which such individuals are subjected must be at all times great. Surely, then, it is not unreasonable to ask that they should enjoy the right of selecting the man in whom they place the greatest confidence; besides which, 'a parish doctor,' as he is termed, is always an object of abhorrence; however skilful, however great the attention received from him by paupers, they always fancy themselves objects of neglect. . . ."

THE SPHINCTER MECHANISM OF THE LOWER END OF THE BILE DUCT*

BY

GORDON GORDON-TAYLOR, C.B., O.B.E., LL.D., F.R.C.S.

Temporary Surgeon Rear-Admiral

That some sphincteric arrangement exists in this region is of course incontrovertible. The obliquity of the bile duct in its passage through the wall of the duodenum, which attracted the attention of Fallopius in the sixteenth century, would seem to indicate an important part played by the muscular coats of the gut in the control of biliary outflow; this obliquity of channel and the marked prolongation of the "portio intestinalis" of the choledochus in certain animals—e.g., sheep, certain whales, seal, walrus, dolphin, leathery turtle, etc.—are very significant. Samson Wright (1940), however, adumbrates a dual mechanism and suggests the existence of additional fibres round the termination of the duct just before it finally reaches the lumen of the duodenum. It is concerning the existence of this special sphincter, its nature, and origin that there appears to be uncertainty.

The precise relation of function to structure may necessitate investigation by several methods of approach; there is no contentious rivalry between the methods of science, and one may prove of value in supplementing the lessons learned from another mode of inquiry, and may help to illumine the dark and more obscure parts of the problem. Various methods of investigation have been utilized by many different workers on the present problem: (1) the lessons from the results of operative surgery in man; (2) the experimental method, including the pharmacological approach; (3) the study of anatomy, including histological and embryological methods; and (4) the comparative-anatomy approach.

Surgical Evidence in Favour of a Special Intrinsic Sphincter

The hepatic infections which appear prone to constitute a frequent aftermath of promising operations for reconstruction of the injured or strictured main biliary channel, when the choledochus or more often the hepatic duct is united by surgical effort to the stomach or duodenum, and the recurrent attacks of cholangitis which are apt to punctuate the after-story of those for whom choledocho-duodenostomy has been performed for other pathological conditions of the main duct, are suggestive of a special sphincter mechanism at the lower end of the bile canal. The presence of such an intrinsic mechanism appears the more probable, since the bilio-digestive anastomoses referred to involve a portion of the alimentary tube apart from the biliary caruncle, and in those cases in which an end-to-end repair of the structured duct is possible and the integrity of the ostium is maintained, ascending cholangitis is less likely to appear. There seems to be something peculiar in the neuromuscular mechanism in this area which is absent in the muscular tissues of the neighbouring stomach or duodenum.

The presence of air in the upper portion of the biliary tree may denote a patent anastomosis, but also indicates the absence of a sphincter controlling reflux into the duct. The readiness with which the contents of a barium meal may penetrate up to the hepatic ramifications of the biliary tree after hepaticoduodenostomy was demonstrated radiologically by Lardennois; no mechanism comparable to that which obtains at the "biliary ostium" is reproduced by any surgical attachment of hepatic duct or choledochus to duodenum.

Mallet-Guy, Auger, and Croizat demonstrated experimentally the constancy and severity of ascending biliary infection which follows any surgical intervention that sections or destroys the sphincter mechanism; Bengolea and Velasco-Suarez (1939) also specially emphasized the frequency of cholangitis as a sequel to choledocho-duodenostomy, and entered a strong plea against its routine performance.

The remarkable immunity (Walton, 1939b) to ascending infection shown by cases of congenital dilatation of the bile duct for which an anastomosis has been performed between such a bile pond and the duodenum may be due to the escape of a certain quantity of the bile through the normal ostium and the preservation of the normality of the sphincter mechanism.

The Experimental Method of Inquiry

Perhaps the greater bulk of the literature relating to the problem has emanated from the experimental laboratory. The intermittent flow of bile from the intact papilla in man and gall-bladder-bearing animals, which contrasts with the continuous dribble in mammals which lack a gall-bladder, is thought to suggest the action of a special sphincter mechanism in the former group. The differing reaction to mechanical irritation of the biliary caruncle in the two mammalian groups which either boast or lack a gall-bladder has been reckoned as betokening divergent sphincter mechanisms; and the dilatation of the extrahepatic ducts after experimental or surgical cholecystectomy has also been regarded by some observers as indicative of some special functioning sphincter in the gall-bladder group and its absence in the other.

Mann and Higgins (1927) pointed out that if the intramural bile duct in animals was dissected away from the duodenal wall, care being taken to remove all the intestinal muscle grossly visible, there remained enough muscle around the lower end of the duct to prevent the escape of bile, even at a pressure greater than the secretory pressure of the liver or that induced by contraction of the gall-bladder: the area of the duct in this experiment which responded to stimulation was limited and restricted. Lueth (1931) expressed his certainty that the intramural portion of the common bile duct possesses a special sphincter mechanism, and even estimated that this sphincter exerts one-third to one-sixth of the total resistance offered to the flow of fluid through the "portio intestinalis."

Considerations of space preclude any complete catalogue and review of the experimental work devoted to the problem, and it would be churlish and impertinent for a surgeon dealing mainly with human anatomy to pass judgment on the labours of those whose approach to the problem bristles with formidable technical difficulties, yet it is not easy to find the truth amidst the fog of conflicting experimental results. Despite the use of methods of inquiry cleverly devised, elaborately staged, and graphically recorded, the experimental investigation of this limited anatomical district is necessarily a somewhat rude insult to the integrity of the extrahepatic ducts, and engenders a certain scepticism and a lack of confidence in the deductions derived therefrom. For example, some disturbance of the sphincter mechanism in man results from a mere choledochotomy, as is evidenced by the presence of pancreatic ferments in the human bile which drains from the bile duct; the escape of granules of carmine, etc., as shown by Bond, also suggests the derangement of sphincter action effected by a minor mundane manœuvre. The accuracy of results in experimental work which involves incision and intubation of the bile duct must therefore be always open to criticism.

---

* The second and concluding part of a Hunterian Lecture delivered at the Royal College of Surgeons of England, June 18, 1942.

The Pharmacological Method of Approach

Major Hilary Long (1942) has ingeniously endeavoured, by means of carefully conducted pharmacological perfusion experiments upon the biliary ducts, to differentiate purely sphincter effects from those produced by the activity of the duodenal musculature, and claims by her research to have demonstrated an intrinsic choledochal sphincter acting "independently" of duodenal tone and peristalsis in the dog. The pitfalls and difficulties of the experimental method have already been sympathetically referred to; yet very suggestive and illuminating is her contention that the concentration of bile salts and the alkalinity of the bile produce relaxation of this special sphincter; thus the sphincter may be closed to the efflux of bile which is not of the appropriate reaction and concentration, and a train of untoward circumstances be inaugurated.

The Anatomical Approach

The arrangement of the muscle fibres round the intramural portion of the duct has been investigated by different workers employing histological methods or the dissection-microscope on material preserved and prepared in diverse fashions. There has been little unanimity of opinion since the time of Oddi, who claimed in 1887 to have demonstrated a more or less distinct band of circular fibres encircling the "portio intestinalis" of the duct, which, apart from some slender loops that lose themselves between the fibres proper of the gut, are almost independent. Hendrickson (1898) as a result of dissection both described and depicted an intrinsic circular sphincter in man, dog, and rabbit; Boyden and his co-workers in text and illustration have described an intricate web of muscle fibres surrounding the duct which are separable into definite collections and for which a very special nomenclature has been coined; nevertheless, these workers neither discuss nor depict any circular fibres near the papillary orifice, such as have been mentioned and figured by Hendrickson, Newman (1931, 1933), and others. Broman (1921) mentioned a well-formed intrinsic sphincter in the foetus of the Antarctic whale, and Helly (1899) also emphasized its existence in human anatomy. On the other hand, Auster and Crohn were unable to demonstrate any distinct intrinsic sphincter.

My colleague Prof. John Kirk kindly interested himself in the subject on my behalf, and investigated *adult and foetal human material* both histologically and by dissection, and has afforded me ready and willing access to his preparations. We have assured ourselves that in no specimen examined histologically was any circular arrangement of muscle fibres found at or near the opening of the common bile duct on the duodenal papilla. Muscle can be seen in considerable amount on the more basal portion of the intramural duct; but this is oblique and longitudinal in its arrangement, and can be definitely and indubitably traced in continuity with the circular muscle coat of the duodenal wall; in other words, when the duct pierces the outer wall of the duodenum it carries in some of the circular muscle fibres of the duodenum, which are now arranged in an oblique and longitudinal fashion in the wall of the duct itself. The muscle of the duct is abundant in its basal intramural portion, and bundles of the longitudinal muscle fibres can be traced into the connective-tissue core of many of the villous processes.

It was subsequently realized that our findings are very closely comparable to those of Dardinkski (1934-5), who reported: (1) the greatest constriction of the common duct is produced by the intestinal muscle; (2) the independent muscle fibres described by Oddi as responsible for sphincteric action are longitudinal or oblique, and not circular. He also (3) drew attention to the muscle fibres in the villi and suggested that they may play an active part, and (4) noted the mucous gland which we had observed as a most conspicuous feature in histological examination of the terminal bile and pancreatic passages. Furthermore, microscope-dissection of the lower extraduodenal part of the common bile duct shows the presence of well-defined longitudinal muscle fibres which pass deep to the longitudinal muscle of the bowel and become directly continuous with the circular coat of the duodenum. The longitudinal and oblique arrangement of the muscle fibres in the duct wall would seem to indicate that the papillary muscle acts as a retractor of the papilla; and this action, in point of fact, can be readily seen in operations in man which involve opening of the duodenum. This initial retraction of the papilla is followed by the biliary efflux from the ostium and inspection of its postero-internal wall.

The muscle bundles in the villi by their contraction may stiffen these structures and secure their closer apposition, in a manner comparable to the disposition of the human fingers assuming what is termed the "accoucheur's hand"; on the other hand, the temporary intermittent shortening of the villous processes by the action of the contained muscle fibres may aggregate them into a clump or cluster which prevents regurgitation of the duodenal contents, and, acting in co-ordination with the circular tunic of the duodenum, temporarily holds up the issue of bile. Kirk and I have also satisfied ourselves that no circular arrangement of fibres exists in the hepatic duct in either adult or foetal material; there is no evidence of an anatomical sphincter here, despite cholangiographic suggestions of a "physiological sphincter" (Mirizzi, 1940).

An embryological approach towards solving the question of a separate intrinsic sphincter has been employed by Boyden and Schwegler (1936, 1937) with exemplary thoroughness. They claim that the musculus proprius of the duct differentiates *in situ* from the mesenchyme and *is not an emanation from the duodenal musculature.* It is admitted that where the duct penetrates the gut wall the margins of the "fenestra" contribute a few scattered fibres to the outer longitudinal coat of the sheath, but that the inner circular coat round the lumen of the duct is exclusively intrinsic in origin. These authors, as a result of their studies of the foetal and adult stages, mention "fasciculi longitudinales," but, unlike Kirk and myself, pay far more attention to an annular sheath of intrinsic muscle round the duct, and also describe a "sphincter ampullae"(!).

The Comparative Approach

Like any other discipline the "comparative" method is not without its dangers and pitfalls: generalizations drawn from the dissection or examination of a single specimen are apt to be misleading: the law of variation obtains in the subhuman as well as in the human type. The concepts of human anatomy are based upon numberless dissections of myriads of material; it is essential that museums of comparative anatomy should assemble ample store material, to be held at the disposal of research workers. The so-called "Physiological Series" of the old Museum of the Royal College of Surgeons of England contained much that constituted an illuminating basis and background of the anatomy of man.

My "comparative" interest in this region concerned itself initially with the involution of the so-called "ampulla," which in point of fact is an infrequent abnormality in man. The beautifully arranged physiological series in the lamented Museum in Lincoln's Inn Fields afforded strong evidence that the "ampulla" is an involutionary anatomical structure, and it may be possible some time to produce and publish morphological evidence in support of this view. But a study of the collection referred to also furnished here and there naked-eye evidence that the muscle surrounding the terminal part of the bile duct originates from the intestinal musculature: elementary embryology would indeed suggest such a derivation.

No comprehensive comparative histological study has been possible during the war, but careful examination of such selected material as time has permitted indubitably confirms the genesis of the muscular sheath of the "ampulla" from the muscular coats of the duodenum in at least certain types; for example, the origin of the bile-duct musculature in the circular coat of the duodenum is apparent in the lion and tiger cub, and Prof. John Kirk has made extensive researches in the cat. In this animal, where the duct pierces the duodenal wall the circular muscular coat becomes greatly thickened and is indeed several times thicker than the circular coat of the bowel at a short distance proximally and distally. In this region where the circular coat is so markedly thickened Auerbach's plexus is distinctly enlarged, and clumps of ganglion cells may be seen collected in that area in much greater numbers than in the duodenal wall elsewhere. The muscular thickening and the concentration of ganglion cells must indicate increased muscular action where the common bile duct penetrates the circular coat of the bowel from without. No sign of any intrinsic circular muscle ring round an ampulla has been discernible. It is hoped that in the future further comparative histological investigation may be carried out. But there is also macroscopic evidence of such a muscular relationship: thus in certain of the Carnivora—e.g., *Viverra civetta*—and in some Pinnipedia—e.g., *Phoca vitulina*—it is abundantly clear even to the naked eye that the muscular coat of the ampullated duct takes origin from the intestinal muscle tunics (Figs. 3 and 4).

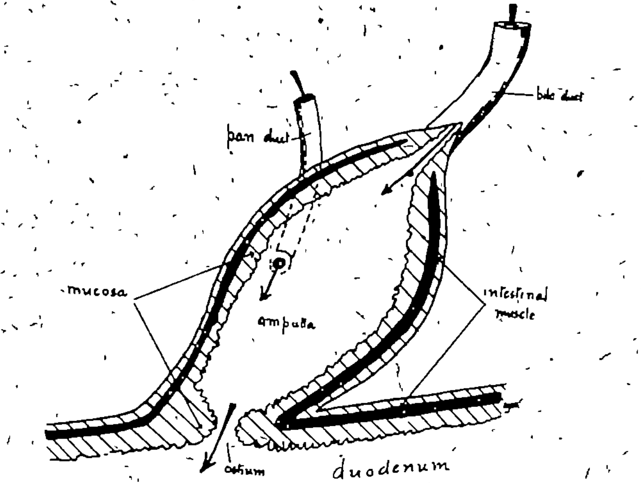

FIG. 3.—Civet (*Viverra civetta*): R.C.S. Museum (store specimen). Wall of ampulla formed by muscle of duodenum, which ceases abruptly at apex of ampulla. No muscle in walls of pancreatic and biliary ducts. (I.e., ampulla = intestinal pouch, not a mere dilatation of lower end of ducts.) (Cross-hatching indicates cut surfaces.)

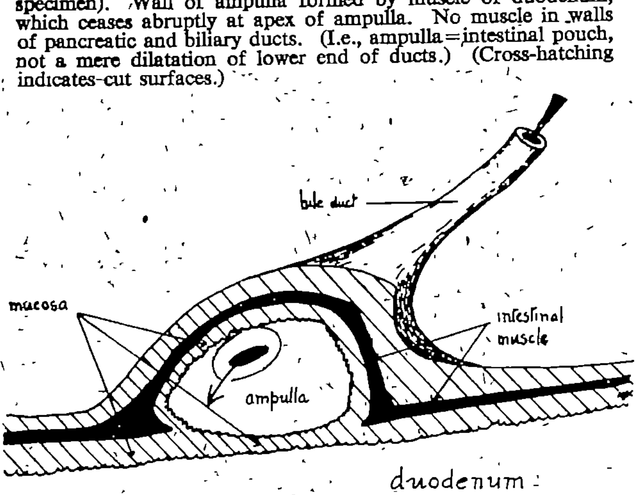

FIG. 4.—Seal (*Phoca vitulina*): R.C.S. Museum (store specimen). Ampulla wall formed of intestinal muscle, which is confined to the pouch and does not extend into the bile duct. (Cross-hatching indicates cut surfaces.)

Summary

This paper comprises two sections of a recent Hunterian Lecture.

It emphasizes the low grade of malignancy of many tumours of the lower end of the common bile duct and adjacent head of the pancreas, and appeals for more radical measures in this type of case. Several personal cases of resection are quoted, and reference is made to those of other surgeons.

The diverse methods of scientific investigation lend support to the view that a special intrinsic sphincter exists at the terminal portion of the common bile duct or the conjoined bilio-pancreatic duct.

The muscle sheath of the duct is derived from the circular muscle tunic of the duodenum.

Although circular muscle derived from the bowel tunics is to be found round the basal portion of the intramural duct, only longitudinal and oblique fibres are present in the distal portion of the papilla. Some of these fibres are prolonged as a core into the villous processes with which the wall of the terminal segment of the duct abounds.

The direction and arrangement of these fibres shows that their action is partly to retract the papilla and partly to erect or to aggregate the villous processes centripetally, thereby preventing reflux from the duodenum and controlling the exit of bile.

There is no circular arrangement of fibres close to the ostium —a reputed disposition credited with mythical properties.

There are few muscular fibres in any of the extrahepatic biliary ducts, and certainly no circular disposition of muscle fibres forming a sphincter in the hepatic duct.

The kindly co-operation of Prof. John Kirk and of Prof. A. J. E. Cave has been invaluable in the preparation of this lecture; my warmest thanks are due to both these friends for all their help so spontaneously and enthusiastically given. Mr. S. R. Scarfe of the Anatomical Department, Middlesex Hospital, has prepared the innumerable histological sections which have formed the basis of part of this inquiry, and to him I am indeed most grateful. My friend Col. A. E. Hamerton has generously afforded me material from the Gardens of the Zoological Society. Surgeon Commander W. A. Hopkins, R.N., and members of the staff of the pathological department of a naval hospital have readily and eagerly granted me facilities for work in their laboratory. Surgeon Vice-Admiral Sir Sheldon Dudley has always a stimulating effect on any worker, and at all times encouraged me, so that the occasional minutes and hours of surgical inactivity inevitable in war have not been idly spent, and an endeavour has been made to carry on, though feebly, the spirit and tradition of the Founder of our Museum, who seized the fleeting hour for Science, even amidst the distractions and disorders of war.

ENTERITIS IN A NURSERY HOME ASSOCIATED WITH GIARDIA LAMBLIA*

BY

G. ORMISTON, M.D., M.R.C.P.Ed.

JOAN TAYLOR, M.B., B.S., B.Sc., D.P.H.

AND

G. S. WILSON, M.D., F.R.C.P., D.P.H.

The following account of a prolonged outbreak of enteritis associated with *Giardia lamblia* (*G. intestinalis*), affecting both children and adults in a nursery home for evacuees, is reported partly because little attention seems to have been paid in Great Britain during recent years to infections with this protozoon and partly because there is reason to suspect that the condition is commoner than is generally supposed.

History

The outbreak occurred in a spacious country-house, referred to as the Grange, used both as a family residence and as a wartime nursery. The domestic arrangements of the two communities were separate, but there was naturally a good deal of communication between the two sides of the house. Consequently, the entire population, numbering 51 in Jan., 1941, was exposed to the infection, and 86% showed signs or symptoms as a result.

---

* A Report to the Medical Research Council from the Emergency Public Health Laboratory, School of Pathology, Oxford.

The infants, 31 in all, of both sexes, and aged at the time of admission from 4 to 16 months, came from poor working-class homes in or about London. They were cared for by eight nurses under the supervision of a matron with special paediatric training. The nursery accommodation was ample and reasonably well adapted to its purpose, and the management of the children very satisfactory, so that a detailed description of the hygienic arrangements may be omitted. The first batch of infants arrived at the home on July 18, 1940, in good health. Included were twin sisters aged 16 months and a boy of 13 months, all of whom had loose stools on July 29; these were the first to be recorded. Within another week 3 more, and within six weeks all the infants, had loose stools. Further infants joined the nursery in Aug., Sept., and Nov., 1940, and in Jan., 1941, and all but 3 became similarly affected within a month—2 within as short a period as seven days and 2 within nine days.

Some of the adults soon began to have diarrhoea as well. Two nurses were attacked early in August, and other nurses, and the family in residence and most of their servants, in the months that followed. Symptoms in the nurses appeared within 10 days to 8 weeks of their arrival. Several months elapsed before some of the house servants had diarrhoea, but this can probably be explained by the fact that they had less contact with the children than the nurses and the private residents.

Between July, 1940, and Jan., 1941, 28 out of 31 infants were affected and 16 out of 20 adults. The more intensive phase of the outbreak extended from Aug. to Dec., 1940, during which time additional children arrived at the nursery in small groups. From Jan., 1941, the acute episodes were less in evidence, but the trouble continued to smoulder until May, when treatment put an end to it.

Symptoms

Infants.—In nearly all cases the earliest sign of infection was looseness of the stools. This did not at first arouse anxiety. The infants were given grey powders and were not confined to bed. A few of them rapidly got worse. The stools became fluid, pea-soup or dark green in appearance, and increased in number up to ten a day. No blood was seen. There was repeated vomiting, dehydration, loss of appetite and weight, and sometimes a rise of temperature to 100° F. In one case at least there was severe abdominal pain and tenderness. Recovery from this acute phase took place in a few days, but was sometimes delayed for two or three weeks. These urgent symptoms appeared quite soon in some of the infants, but in others they were preceded by a mild form of diarrhoea for several weeks. In all, 9 infants were severely ill; 2 of them had to be removed to hospital, where they died. In the remaining 19 infants the initial symptoms were less striking. Once started, the enteritis continued for a few days to a month or more. The stools were generally loose, though persistently fluid in a few cases, brown or green, often with a noticeable excess of mucus, but without blood, and numbering two to four in the 24 hours. Some of the infants vomited on several consecutive days or intermittently. Systemic effects were mild, and the infants were not confined to bed. A chronic stage followed the initial acute or subacute attack, except in the 2 fatal cases and in 2 that cleared up completely. In 7 cases diarrhoea was persistent till therapy was instituted. Soft green or brown stools were passed every day. One of the patients had loose green stools for seven months, and 3 whose stools were always fluid suffered impairment of appetite and growth. In the remaining cases the diarrhoea was intermittent, taking the form of subacute attacks lasting for two to four days or longer, every few weeks. Again the stools were loose, green or brown, or else fluid. As the attacks subsided in some of the infants the stools became large, soft, and white before they were normal.

Adults.—Of the adults affected 6 were nurses, 4 were members of the resident family, and 6 were servants in their employment. Only 3 nurses and 1 servant appear to have been free from symptoms. In general, members of the nursing staff were the first to be affected, and the domestics the last. The onset was somewhat different from that in the children. There was no prodromal period of mild diarrhoea, but a sudden acute and usually violent attack of diarrhoea accompanied by more or less severe abdominal pain. The stools were dark, very loose or fluid, and numbered 10 to 20 or more in the 24 hours. Blood was never noticed. The pain was of a griping nature, usually in the lower abdomen, but in some patients located in the epigastrium or the right hypochondrium. Vomiting was frequent. Additional symptoms in order of frequency were giddiness, loss of energy, weakness or faintness, anorexia, headache, nausea, flatulence, backache, and fever. When the attack was over there was usually a rapid convalescence. About one-third of the 16 adults affected had one attack, a like proportion had two, and the remainder three attacks before treatment. The interval between the attacks varied from four to eight weeks. One nurse had prolonged attacks at short intervals over a period of three months. She kept at her work, but suffered from lack of energy and "pain in the stomach and back, especially when carrying anything or making the cots." Two other nurses stated that after their last attack they had never been really free from diarrhoea, and often felt weak and faint. These nurses had apparently entered a chronic symptomatic stage of the infection like the children. The other adults felt perfectly well between attacks, and many of them remained free of symptoms for some months. No physical examination of the adults was made either before or after treatment, as all were engaged in their affairs and none was acutely ill when seen.

Bacteriological Investigations

At the request of Dr. Cowan, medical officer of health, Gloucestershire County Council, the Oxford laboratory was asked to investigate this outbreak. The Home was first visited on Jan. 29, 1941. Bacteriological examination of the stools at a neighbouring laboratory had shown organisms of the paracolon group in several specimens, and it had been suggested that these were probably water-borne. There were two water supplies available for the nursery, and both had apparently been condemned by local analysts. Our investigation of the two water supplies showed that they were collected from a hillside under almost perfect conditions, and both bacteriological and chemical examination confirmed their freedom from excretal pollution.

There were two milk supplies—one to the nursery and the other to the private residents. A sample from the nursery supply proved to be of relatively poor bacterial quality. Since, however, all milk and water for the children was boiled, it was difficult to believe that they could be responsible for the outbreak.

Specimens of faeces from 25 children and adults were examined for organisms of the dysentery and *Salmonella* groups, with completely negative results. Blood serum from 4 of the adults was tested for agglutinins against organisms of the *Salmonella*, dysentery, *Brucella*, *Proteus X*, and *Leptospira* groups—again with negative results. Further faecal specimens were obtained in February from 8 children with recent or current diarrhoea, special arrangements being made for their receipt at the laboratory within a few hours of collection. These were examined for protozoa. Five of them contained *Giardia lamblia* in either the free or the cystic form, three in very large numbers. Since, according to Dobell (1921), the infection rate in this country is between 4% and 9% for adults and 14% and 40% for children, it seemed desirable to obtain further information on the frequency of this parasite in the Grange. Accordingly on March 3, 1941, specimens of faeces were examined from 29 children and 22 adults.

The method we used consisted in rubbing up a small portion of the faeces on a slide in a 1% solution of eosin with a wooden toothpick or platinum spatula, so as to make a moderately opaque suspension. A cover-slip was applied, and the preparation was examined at once under a 1/6-inch objective. This method has the advantage of providing a pink background, against which the unstained protozoa can be distinguished readily by contrast. *Giardia* appears as a pear-shaped body about 10 to 20 μ long by 6 to 10 μ wide in the free form, and 10 to 13 μ by 8 to 9 μ in the cystic form, having a faint bluish tinge. Little structure is visible, but if a second preparation is made in a drop of Lugol's iodine, the nuclei, the axostyles, and other details can often be seen. The results of our examination are recorded in Table I.

TABLE I.—*Frequency of Giardia lamblia in Faeces*

	No. Examined	No. Positive	% Positive
Children ..	29	13	45
Adults ..	22	6	27
Total ..	51	19	37

The proportion of children carrying *Giardia* was higher than that of adults. Taking both together, no less than 37% of the 51 persons examined proved to be infected. An analysis of these figures was made in relation to (1) the presence of loose stools at the time of examination, and (2) a history of continual or intermittent loose stools for some months previously (Table II).

TABLE II.—*Frequency of Giardia lamblia in Relation to Diarrhoea*

	No. of Patients	Positive		Observed % Difference between the Two Groups	Standard Error of this Difference	Observed % Difference divided by its Standard Error
		No.	%			
A. Loose stools at time of examination . .	7	5	71	39	18·5	2·1
B. No loose stools at time of examination . .	44	14	32			
C. History of intermittent or continual loose stools for some months . .	11	9	82	57	13·5	4·2
D. No history of intermittent or continual loose stools for some months . .	40	10	25			

From Table II it is seen that the proportion of persons harbouring *Giardia* was more than twice as great in those with loose stools at the time of examination as in those without. The numbers, however, are small and the odds against getting such a distribution by chance alone are not more than 27 to 1. The proportion of persons harbouring *Giardia* was more than three times as great in those with a history of intermittent or continual loose stools for some months as in those without, and the odds against such a distribution are over 37,000 to 1. There appeared, therefore, to be little doubt that the association of *Giardia* with chronic enteritis was more than coincidental. When it is remembered that Groups B and D were not strictly control groups, practically all the patients in these groups having suffered at one time or another from diarrhoea, the association becomes even more significant. It is hardly necessary, however, to point out that such an association does not prove the causal relationship of *Giardia* to the enteritis, but it does add weight to other evidence that may be brought in favour of this assumption.

Treatment

Since Brumpt (1937) recorded his finding that mice infected with *Giardia muris* could be rapidly freed from infection by the oral administration of quinacrine, several workers have successfully applied this treatment to human beings. Galli-Valerio (1937), Love and Tayloe (1940), Voltrina (1941), Nutter, Rodaniche, and Palmer (1941), and Hartman and Kyser (1941) used atebrin; but de Muro (1939) and Grott (1939) obtained better results with acranil, a hydrochlorate of a new acridinic compound prepared by Bayer. Atebrin and quinacrine, it may be noted, are different names for the same substance. Chemically this substance is an acridine compound related to the antimalarial plasmoquine, but differing from it in the substitution of the acridine for the quinoline nucleus; it has therefore no direct relationship to quinine. Since acranil was unobtainable we decided to try quinacrine.

Six children who were heavily infected with *Giardia* were transferred to a cottage some distance from the Grange and put in charge of two nurses. One of these was heavily infected; the other, who had joined the staff only three weeks previously, had not suffered from enteritis and had no *Giardia* in her stools. All food was prepared in the cottage, and no communication, except by the matron, was permitted between the inhabitants of the cottage and those of the Grange. Before treatment began, and again after the conclusion of the first course of treatment, the cottage was thoroughly cleaned and disinfected.

Tablets containing 0.1 g. of quinacrine were obtained from Messrs. May and Baker. The children, all of whom were under 2 years of age, were given one-sixth of a tablet, and the infected nurse one tablet, three times a day for five days. As the drug is very bitter the tablets were not pulverized, but were mixed with the food at the end of a meal. A drink of milk was given immediately afterwards. The nurses were instructed to keep the children's bowels well open and to watch for toxic symptoms. These comprise persistent headaches, severe abdominal pain, cerebral excitement, and acute restlessness, and are best treated by the administration of purgatives, large doses of alkali, and plenty of sugar. The first course of treatment lasted from May 12 to May 17, 1941. Examination of the stools on May 19 showed that they were all free from *Giardia*. As none of the patients had suffered from toxaemia, and as the probable duration of the apparent cure was in doubt, it seemed wise to repeat the treatment. This was carried out between May 21 and May 26. Samples of faeces collected on the last day again proved negative.

The success of this treatment, as indicated by the disappearance of *Giardia* from the stools, seemed to warrant its application to the remainder of the children at the Grange. Accordingly 25 children, of whom 13 were known to be infected, and 13 adults, of whom 5 were known to be infected, received a first course of treatment between June 5 and June 10, and a second course between June 15 and June 20. Stools taken on June 11 after the first course and on June 24 after the second course all proved negative. Before and after the first course the nursery portion of the Grange was disinfected so far as possible in order to reduce the opportunity for reinfection. Apart from insomnia in some of the adults, and occasional slight yellow coloration of the skin and urine, no untoward effects were caused by the drug.

The stools of many of the patients were re-examined at intervals up to Feb., 1942. During this time only two of the previously positive children relapsed or became reinfected—it was impossible to say which. One showed a few *Giardia* in the stools in Aug., 1941, and the other a very scanty infection in Feb., 1942. Two fresh cases, however, were detected in children and one in a nurse whose stools had been repeatedly negative. These occurred in July and Aug., 1941, and in Feb., 1942. All five cases cleared up at once after a single course of quinacrine treatment. So far as the elimination of *Giardia* infection was concerned the treatment was undoubtedly successful. The failure to achieve complete sterilization may perhaps have been due to the presence of infection in two or three of the adults who were unwilling either to provide stools for examination or to undergo treatment.

Clinical Results of Treatment

Before treatment started, and again 8 to 9 months later, the children were physically examined, and blood counts were made on a number of those who were most heavily infected. At the first examination, 5 to 9 months after their admission, most of the 31 infants were fairly well nourished, but 26% had skin infections of one type or another, including eczema, and in 40% muscle tonus was poor. Many of them had diarrhoea or loose stools at the time, or gave a history of enteritis in the recent past. At the second examination their nutritional state and general well-being had improved; only 4% now had skin infections, and muscle tonus was good in all but 16%. Diarrhoea had ceased for several months and loose stools were unusual. We had hoped to find out whether the beneficial effect of treatment was reflected in the rate of growth, but we were unable to make use of the figures available because the weight and height of the infants were taken at irregular intervals, and the numbers falling into appropriate age periods were too small for comparison with normal standards. In the adults diarrhoea had likewise ceased, and those who had previously suffered from abdominal discomfort, weakness, giddiness, and anorexia now, appeared to be quite well again.

Before treatment the average number of red blood cells in 7 of the infected infants studied in April, 1941, was 4,700,000 per c.mm., and of white blood cells 8,100 per c.mm. After treatment the corresponding figures obtained in Feb., 1942, on the same infants were 4,800,000 per c.mm. and 11,000 per c.mm. respectively. These differences are of little importance. The haemoglobin content of the blood, on the other hand, showed a considerable rise. Before treatment the figures varied from 60 to 88%, with an average of 74%, and after treatment from 80 to 94%, with an average of 85%, thus showing an average increase of 11%. Before treatment some degree of hypochromasia, polychromasia, and basophilic stippling was common, whereas after treatment the red cells were normal except in one child in which they showed slight anisocytosis. A remarkable feature of the differential white cell counts in Feb., 1942, was the finding of a mild degree of eosinophilia, varying from 4 to 14%. Observations on two occasions for *Enterobius* made by the cellophane swab technique were negative, so that a helminthic infection seems improbable. What the explanation is must remain undecided, but it is thought worth while reporting this finding in case others meet with a similar degree of eosinophilia in *Giardia* infection treated with quinacrine.

Discussion

It is not our purpose here to discuss in detail the evidence for and against the pathogenicity for man of *Giardia lamblia.* Those wishing for fuller references should consult papers by Lyon and Swalm (1925), Véghelyi (1938), Manson-Bahr (1940), and McGrath, O'Farrell, and Boland (1940). Opinion is divided between those who regard this organism as a harmless parasite and those who believe that it may give rise to symptoms of disease.

So far as children are concerned one of the most careful of recent studies is that of Véghelyi (1938, 1940), who made observations on 92 infected and 92 control children aged 2 to 17 years at the children's clinic, Budapest. He found that in the infected subjects the occurrence of anorexia, headache, dizziness, abdominal pain, irregular bowel movement, and anaemia was much more frequent than in the controls. Of the infected children 86% were below average weight and 75% showed signs of disease. Studies in the laboratory revealed that fat absorption was defective, and that excretion of biliary pigment in the urine was much below normal. Véghelyi attributes this to the mechanical effect of the parasites in covering to a greater or less extent the wall of the intestine and rendering it impermeable. The resulting interference with absorption he regards as being sufficient to account for the anaemia and retardation of development. Great clinical improvement followed eradication of the organism by acetarsone.

Hartman and Kyser (1941), who described 100 cases of *Giardia* infection at the Mayo Clinic, all but 5 of the patients being over 14 years of age, found that 89% had symptoms of illness. The commonest complaints were diarrhoea and abdominal pain. In a small number of cases which were treated with atebrin and followed up, clinical cure resulted. Nutter, Rodaniche, and Palmer (1941), in a study of 14 infected adults, noted the following symptoms in order of frequency: diarrhoea, fatigue and weakness, abdominal pain and flatulence, blood in the stools, insomnia, dizziness, nervousness, and loss of weight. The symptoms disappeared after treatment with atebrin.

Our own observations support the conclusions of other recent workers in indicating that *Giardia* infection may not be without a detrimental effect on the health of the patient. It is difficult to estimate the exact part played by this organism in causing enteritis at the Grange, since other causes cannot be excluded with certainty. During the last two or three winters a disease, which for want of a better term we refer to as "non-specific enteritis," has been common in many parts of the country, giving rise to acute transient attacks of vomiting and diarrhoea. Opportunities for a thorough examination of cases have been few, but so far we have failed to find any evidence of bacterial or protozoal infection. This disease may have been responsible for some or all of the acute cases of enteritis at the Grange, though probably not for the chronic cases. The higher frequency of *Giardia* in the patients suffering from chronic diarrhoea than in those with normal stools is very suggestive; but too much weight should not be put on this finding alone, since there is presumably a greater chance of finding cysts in the faeces when the stools are loose than when they are normal. Taken, however, in conjunction with the clinical improvement after treatment, it does suggest fairly strongly that the presence of *Giardia* was more than a fortuitous association.

Undoubtedly one of the factors that has most influenced recent opinion in favour of regarding *Giardia* as potentially pathogenic is the disappearance of symptoms, even of long-standing diarrhoea, after treatment with one of the new specific remedies. Such an observation was not possible for a worker like Boeck (1927), who, on statistical grounds alone, was unable to satisfy himself that *Giardia* was more than a harmless parasite.

How infection was introduced into the Grange is not known. The matron who opened the nursery, and who shortly afterwards left, was suffering from enteritis on her arrival; she may have been responsible, but this can be no more than a surmise.

Summary and Conclusions

An outbreak of enteritis, much of it of a chronic type, affecting a high proportion of both children and adults in a residential nursery for evacuees is described.

Giardia lamblia was found in 71% of children and adults having loose stools at the time of examination and in only 32% of those with normal stools.

Giardia lamblia was found in 82% of children and adults with a history of intermittent or continual loose stools for some months and in only 25% of those without such a history.

Cure of the infection was quickly and successfully accomplished by the use of quinacrine, given in two 5-day courses.

The symptoms—chronic diarrhoea and some degree of anaemia in the children, and diarrhoea with giddiness, loss of energy, anorexia, headache, and epigastric discomfort in the adults—disappeared after treatment, and the general nutrition of the children improved.

The high frequency of *Giardia* in the stools of the patients with long-standing diarrhoea and the favourable effect of treatment suggest that this organism may have been responsible for the chronic enteritis observed in the nursery. Further observations, however, are necessary to establish the exact degree of pathogenicity of *Giardia* for man.

We should like to express our thanks to Dr. Cowan, Dr. Goodwin, Dr. Gordon, Lady Ismay, and Sister Houchin for their generous help in this investigation We are particularly indebted to Prof. Leiper of the London School of Hygiene and Tropical Medicine not only for his frequent advice but for showing us an advance copy of the report to the Medical Research Council on the incidence of protozoa and helminths in the faeces of certain groups of the population in this country which Miss Young made while working in his department

F. Clifton and S. M Laird (*J R.A M C.*, 1941, 77, 318) record two cases of acute meningococcal conjunctivitis in soldiers aged 21 and 23. In both a diagnosis of gonococcal conjunctivitis had been made before admission to hospital, but the absence of any evidence of infection in the genito-urinary tract suggested that the correct diagnosis was one of meningococcal conjunctivitis. One patient had received sulphapyridine before cultures were made, but in the second case the diagnosis was confirmed by bacteriological examination. Neither case showed clinical evidence of involvement of the cerebral nervous system.

TIETZE'S DISEASE

(NON-SUPPURATIVE NON-SPECIFIC SWELLINGS OF RIB CARTILAGE)

BY

A. MORTON GILL, M.D., M.R.C.P.

R. ARDEN JONES, M.B.

AND

LEO POLLAK, M.D.Vienna

(From the Medical Division of an E.M.S. Hospital)

In 1921 Tietze described 4 patients aged from 28 to 50, 3 females and 1 male, who all showed the same clinical picture—viz., swellings of costal cartilages of insidious onset associated with little or no constitutional disturbance, spontaneously painful, and with a prolonged course characterized by fluctuations in the size and tenderness of the swellings. Though one case was followed for over a year, no signs of suppuration developed. The lesions were firm and were confined to the cartilages, which appeared to be expanded locally. The skin over them was normal and freely movable. In one case the intercostal space was filled by the mass. In two patients, aged 42 and 50, radiographs showed calcification of the cartilage, but this may have been coincidental.

In reporting these cases Tietze stressed his ignorance of their nature and the fact that, although he had encountered them all in a short space of time, he had not previously seen a similar condition and could find no reference to earlier descriptions of such cases. Following Tietze's paper, Harttung (1923) described a very similar case which he also had seen in 1921. Radiographs disclosed no changes, but biopsy of part of the diseased cartilage revealed calcification and fibrosis. He referred also to another case reported in 1921 at the Medical Society of Breslau by Froehlich, in which four rib cartilages were involved and which had developed during the course of one year. At the same meeting Kuettner, in the discussion on this case, mentioned several similar cases, in one of which biopsy showed small nodules consisting of fibroblasts and many giant cells.

No further references have been found in the literature since that time, except for a paper by two Japanese authors, Satani and Fujii (1937), who reported 9 cases of Tietze's disease occurring in under-nourished women. Radiographs showed in one case atrophy of the rib cartilage, and in another shortening of the rib and calcification of the cartilage; in all other cases radiology revealed no abnormality. Biopsy in these cases revealed fibrosis, ossification, and atrophy, there being neither granulation tissue nor pus.

During the last few months we have observed 5 young soldiers showing the syndrome described by Tietze, and owing to its rarity we have considered these cases worthy of record. That this condition should have been encountered so frequently in such a short period indicates that at present it is no longer so rare as the scarcity of references suggests. Personal communications tend to support this contention and confirm its former rarity.

Case Reports

Case 1. Aged 27.—Six days before admission the patient had noticed a tender swelling in the left upper chest, followed three days later by malaise, shivering, fever, cough, and pain in the left chest. Previous health good. On admission: temperature 102°; signs of bronchopneumonia at both bases. There was a visible swelling of the second left costal cartilage at the costo-chondral junction. This was of firm elastic consistency, and arose from the second cartilage, but its upper limits were ill-defined and extended upwards to become continuous with the first costal cartilage. It was tender on pressure, but not spontaneously painful. The overlying skin was normal. Radiographs showed no abnormality. With treatment, including sulphapyridine, the bronchopneumonia resolved, but the lump, though less tender and slightly smaller, remained four weeks after the onset. However, when last seen, some four weeks later, there remained only a slight thickening of the costo-chondral junction and there was no tenderness. *Investigations:* Blood W.R., negative; white cell count and differential, normal; B.S.R., normal; sputum, nothing significant; Widal, negative.

Case 2. Aged 24.—Admitted complaining of cough and pain in the left chest, the latter of two weeks' duration. A comrade had called his attention to a lump in the left upper chest at the time of onset of the pain. On admission he was afebrile, and presented the signs of chronic bronchitis and emphysema. A swelling was visible at the second left costo-chondral junction—firm, smooth, and tender on pressure. Spontaneous pain was not present. The overlying skin was normal. Three weeks later, when last seen, the lump was smaller and was no longer tender. *Investigations:* No material could be obtained on needling; culture, sterile; radiograph, negative; Widal, negative; white cell count and differential, normal; B.S.R., normal; sputum, pneumococci predominant; blood W.R., negative.

Case 3. Aged 21.—Developed bronchitis following appendicectomy, and, five days later, pain in the left chest. Temperature 99°. Six days after this he noticed a swelling of the chest, and on examination there was a visible prominence in the region of the seventh rib cartilage, extending about 2 in. along the costal margin and involving the sixth and eighth cartilages. The swelling was hard, and was confined to the cartilages, the intercostal spaces being normal. On discharge some three weeks later the tenderness had gone, but the swelling was still present. As in the previous cases, all investigations were negative.

Case 4. Aged 29.—He had noticed, ten days after pneumonia, a painful tender swelling in the right upper chest. This to a large extent subsided during the next two months, but a month later, following a common cold, it reappeared, and on admission to hospital a diffuse, smooth, firm, tender, ill-defined swelling was visible and palpable in the right upper chest, involving the first, second, and third costal cartilages and filling up the intercostal spaces. Laterally it extended to the anterior axillary line. The overlying skin was normal. There was no fever. This patient has been observed over a total period of nine months, during which time the pain and tenderness, and the size of the swelling, have altered only slightly, the condition remaining substantially unchanged to date. Occasionally there has been fever up to 99°. *Investigations:* B.S.R., 8 mm. in 1 hr. (Westergren); white cell count, normal; blood W.R., negative; Widal, negative; blood calcium, normal; radiographs showed soft-tissue shadow in the region of the swelling, but no bony abnormality; needle exploration, negative.

Biopsy of Case 4 (Mr. John E. Rowlands).—At operation an incision was made directly over the third right costal cartilage extending 4 in. laterally from the edge of the sternum. There was a spindle-shaped enlargement of the cartilage. The intercostal spaces above and below were encroached upon by this swelling, but were clearly definable from it. The tissue of the spaces was oedematous and abnormally vascular, but was not infiltrated by the tumour. The swelling was incised and a wedge-shaped piece removed. It had the appearance of normal cartilage.

Histology of Case 4 (Dr. A. M. Barrett).—The section showed an unmistakable resemblance to cartilage, the cells being enclosed in spaces in the typical cartilaginous matrix. Along one border (apparently the periphery of the nodule) the cells were flattened and small, and at the extreme edge here the appearance of the tissue approached that of collagenic fibrous tissue; elsewhere in the section the cells were for the most part much larger, and the matrix stained more deeply with haematoxylin. Here, too, the cells were not arranged so regularly in pairs, groups of 6 to 8 cells being frequent. A few rather wide blood spaces and more abundant smaller ones were present; also areas (apparently corresponding to the opaque streaks seen with the naked eye) having a fibrillar structure, and as the fibres stained deep red with van Gieson's stain they were presumably collagen fibres. There was no evidence of inflammation.

Conclusion.—The nodule was composed of cartilage, and on histological grounds alone it would be difficult to say that it was not a piece of normal costal cartilage. However, it would do equally well for a chondroma.

Case 5. Aged 19.—Developed rheumatic fever with pneumonia following tonsillectomy, and seven weeks later complained of pain in the second right costo-chondral junction, examination of which revealed a firm tender swelling in every way similar to those previously described. Ten days later the pain and tenderness had disappeared, but a slight enlargement of the costo-chondral junction persisted. As in the other cases, all investigations were negative.

Commentary

In an analysis of the relevant literature it is unnecessary to refer to the frequent accounts of osteomyelitis of ribs due to typhoid, tuberculosis, syphilis, or pyogenic infections, as in the cases here reported there was no evidence of any bone disease. With regard to conditions confined to rib cartilage, Staehelin (1940) remarks that little is to be found on this subject in the literature, and we have been unable to trace any reports in English of cases similar to the above.

It is evident that, clinically, the cases here recorded closely resemble those described by Tietze and subsequent authors, and it seems probable that they represent the same morbid entity. The association with respiratory tract infections has not previously been noted. In each case the swelling was noticed by the patient himself or by a friend, and clinically it could not be disregarded. No fever which could not be attributed to other causes was present, except in Case 4. In each instance the swelling persisted for some time after the respiratory infection had subsided, and we were unable to observe complete return to normality in any case before discharge from hospital; indeed, Case 4 still presents symptoms and signs nine months after the onset. Special investigations have failed to throw further light on the aetiology of the syndrome.

With regard to the morbid anatomy, in a description of the biopsy findings Tietze writes: "The histological examination shows chondral tissue, the irregular arrangement of which suggests neoplasm, but there are no signs of malignancy. I therefore removed the entire mass, which consisted of two cartilages and part of the sternum. To our surprise the cartilages were not abnormal; the soft tissues, perichondrium, muscles, fascia, and ligaments were thickened, but microscopically did not show any inflammatory changes. The cartilages showed histological changes, described above, and here and there calcium deposits and dissolution into fibres." The similarity of this description to the findings at biopsy in Case 4 of our series is striking.

In discussing the aetiology Tietze tentatively suggested that the condition represented a dystrophic change in the cartilage analogous to the bone disease of nutritional origin which was prevalent in Germany in the early 1920's; but there has been no evidence of malnutrition in our patients, all young soldiers of good physique.

We cannot throw any light on the pathology of these swellings. Tietze's cases were all observed at a time when nutritional conditions in Germany were at their lowest ebb. This does not entirely apply to our cases, since, although the national dietary has altered, it is agreed that evidence of general malnutrition is lacking. Nevertheless, qualitative changes of which we are ignorant may be of aetiological significance.

Summary

An account is given of a syndrome first described by Tietze in which non-suppurative non-specific swellings appear affecting rib cartilage, and 5 cases are added to the 16 already recorded. The association with respiratory tract infections has not previously been noted.

Thanks are due to Dr. F. R. Berridge for the radiological examinations and to Dr. O. Morrey for all other special investigations. Our thanks are also due to Mr. John E. Rowlands and to Dr. A. M. Barrett.

D. Skinner and J. E. Edwards (*New Engl. J. Med.*, 1942, **226**, 8) record two cases of subacute bacterial endocarditis caused by an enterococcus in men aged 72 and 60. In the first case symptoms of endocarditis followed prostatectomy, and death took place seven months later. The necropsy showed typical vegetations on the mitral, aortic, and tricuspid valves. The organism (strain A) was recovered from the blood, vegetations, and an extracted tooth. In the second case the symptoms developed in a patient who had had cardiac decompensation for six years. The necropsy showed old rheumatic heart disease with vegetations on the mitral valve. The organism (strain O) was recovered from the blood before death and from the vegetations post mortem.

THE CHEMICAL LUMINESCENCE TEST FOR BLOOD

FORENSIC AND CLINICAL APPLICATIONS

BY

JOHN McGRATH, M.D., M.Sc.

(*Department of Medical Jurisprudence, University College, Dublin*)

Although it is now some years since Specht (1937) first suggested the use of chemical luminescence for the identification of suspect blood-stains, it would seem that no references to the method have as yet appeared in the English literature. This reaction has been of considerable practical value in many technically difficult medico-legal cases and merits description. Its forensic use has led to other applications, and the clinical adaptation now described is simple and very delicate, though it has the disadvantage that it must be observed in the dark.

Gleu and Pfannstiel (1936) described the preparation of 3-amino-phthalic-acid-hydrazide-hydrochloride, and indicated that the alkaline solution, with the addition of hydrogen peroxide or sodium peroxide, produced a typical chemical luminescence with haematin. This reaction is the basis of the luminescence test for blood. One of two solutions may be used; they yield identical results:

A.	3-amino-phthalic-acid-hydrazide-hydrochloride	1 g.
	Sodium peroxide	5 g
	Distilled water	1,000 ml.
B.	3-amino-phthalic-acid-hydrazide-hydrochloride	1 g.
	Sodium carbonate	50 g.
	Hydrogen peroxide (10 vol.)	50 ml.
	Distilled water	1,000 ml.

These solutions may show a trace of inherent luminescence. This is of no practical disadvantage, but may, if desired, be eliminated by the addition of a trace of indazolon-4-carboxylic acid. The solutions are effective when freshly prepared, and remain usable for years by the addition of about 10% of 20-vol. hydrogen peroxide to reactivate the quantity of stock solution required for a particular test.

Forensic Application

In medico-legal cases blood-stains are normally identified by close inspection; a chemical test such as the benzidine reaction to exclude negative stains; positive identification of blood spectroscopically and perhaps with the help of various microscopical preparations; determination of the source of the blood by means of the precipitin reaction; and, in suitable cases, possibly identification of the blood group. In a number of cases, however (and not infrequently those in which the evidence as to blood-stains may be of the utmost value), the stains may be obscured for various reasons and the discovery of their position and content may be attended with more or less difficulty. The stains may be small in amount; they may be mixed with mud or ashes, or other interfering substance; they may have been more or less cleaned away off, say, dark or dirty clothes, off the ground, carpet, or walls, or off a weapon, and traces only may have remained in crevices or cracks; they may have been irregularly distributed in small amounts or difficult to discover on the ground, on dark or rusty or soiled or painted objects, or in cellars or other places not easily susceptible to complete and thorough examination; they may have been changed by temperature, weather, and age. In still other instances the blood may be mixed with or simulated by other stains such as paint, oil, fruit juices, rust, etc. In these cases of difficulty the luminescence test is of especial value.

The solution is introduced into an all-glass pressure-spray designed to produce a fine mist from a watery solution. When this mist falls on a stain containing haematin the result is a marked bluish-white luminescence which is clearly visible in the dark. The luminescence persists for some minutes and can readily be photographed. Very fresh blood-stains, containing little haematin, show little luminescence; but the older the stain, and the greater the proportion of haematin consequently present, the more marked and clear is the light effect. The method we use is to spray the suitably arranged suspect articles in a dark-room, or, in a house, to arrange for the room or area to be darkened or to wait for night.

We have experimented with a very wide variety of substances, and have found the reaction to be specific. There is no reaction with serum, bile, sputum, pus, seminal stains, pleural fluid, earth, faeces, fresh or rotting vegetable material, various paints, oils, metals, wood, wax, shoe-polish, or various other substances. Very slight traces of blood-stains containing haematin, and not detectable to the naked eye, are readily apparent with the luminescence test. Nevertheless, in the present state of knowledge it is not suggested that this test should be used as a final specific test for blood. After the site and extent of the stain have been determined, it is essential to proceed through the complete routine examination.

The luminescence test has a special value in this respect—that after its application to detect the site of the blood-stain all of the further necessary tests may be applied to portions of the stain. The spray allowed to fall on the stain is preferably kept minimal in amount, and after marking or photographing the stain it is allowed to dry. The stain is then available for all the usual tests, and we have been unable to detect any difference in the reactions obtainable in stains which have been sprayed with the reagent and allowed to dry and those which have not been so treated. Nevertheless, as an additional safeguard, and to eliminate all possibility of error, we have in practice invariably adopted the precaution of running a control from a portion of the article which has been sprayed but which shows no evidence of staining.

Clinical Application

In the most direct and simple form of the test the fluid or suspension of the material suspected of containing blood is placed in a test-tube. A small amount of the activated stock solution is added, and the resultant fluorescence, if any, is observed in the dark. Faeces may be dried on a slide, and the test solution poured over it as with the benzidine reaction commonly employed.

A positive result depends on the formation of haematin from the blood originally present in the suspect material, and the greater the amount of haematin present the more marked is the reaction. The delicacy of the test in the presence of fresh blood may be enhanced in the following way: To the suspect fluid or suspension are added a few drops of NaOH solution (about 30%), the tube is shaken and haematin is thus formed; the addition of the test solution will then produce a marked reaction if blood is present. Warming increases the brilliance of the fluorescence but shortens the duration.

So employed, the test is remarkably delicate, and will show a clear positive reaction with blood in dilutions over one in a million.

CARDIAC MASSAGE

AN EXPERIMENTAL STUDY

BY

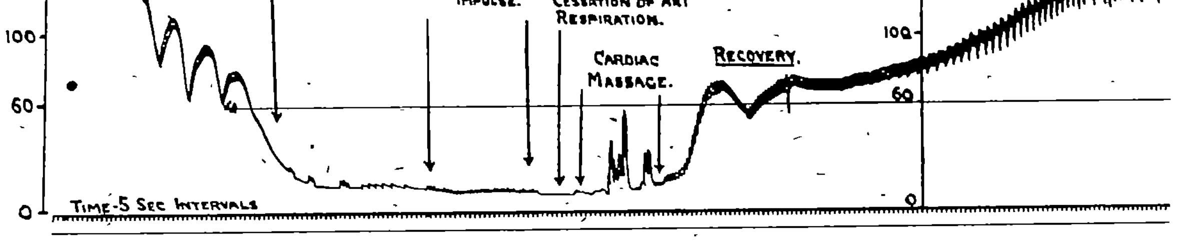
GEORGE A. POLLOCK, M.S., F.R.C.S.Ed.

(*From the Wilkie Surgical Research Laboratory, University of Edinburgh*)

In the treatment of collapse under anaesthesia Hamilton Bailey stressed the importance of early and prolonged cardiac massage in addition to artificial respiration; the present record demonstrates this from the experimental side.

During an experiment on haemorrhagic shock a cat collapsed from an overdose of ether, after the right carotid artery had been cannulated and the respiratory tambour adjusted, but before bleeding had been begun. Immediately before the collapse respirations were 8 a minute and the blood pressure was 150 mm. Hg. In 6½ minutes respiration had ceased and the blood pressure fell to 14 mm. Hg. Artificial respiration was given by means of a pump; while this was being carried out impulses transmitted to the heart from expansion and collapse of the lungs were registered as minor fluctuations in the blood-pressure tracing. When artificial respiration was stopped these transferred fluctuations also stopped, and there was no sign of either respiratory or cardiac recovery.

So certain was I the cat was dead that I was beginning to dismantle the apparatus, when I decided to try the effect of direct cardiac massage. Two minutes 40 seconds after breathing and heart had stopped, the heart was compressed regularly between the fingers of the left hand, which could be pushed up under the left costal margin, and the right hand, which pressed downwards on the left thoracic wall. After 40 seconds an irregular rhythm returned to the heart; this was registered as an irregular fluctuation on the blood-pressure tracing. Massage was continued for 1½ minutes, after which the heart began to beat regularly. The artificial-respiration pump was reconnected and the respiratory tambour adjusted. For one minute the heart maintained its recovery rate; but after the blood pressure had reached 74 mm. Hg it began to fall, as respiration had not been re-established. Artificial



respiration was begun 15 seconds later (or 1 minute 15 seconds after the heart had started to beat). The blood pressure fell for 15 to 20 seconds longer, to 54 mm. Hg, and then rose steadily. Artificial respiration was continued until, after 1 minute, voluntary spasmodic respiratory efforts began. Nine minutes after the first irregular cardiac contraction the blood pressure had risen to 132 mm. Hg, and there was a corresponding improvement in respiration and pulse pressure.

The tracing gives a graphic record of the sequence of events, and demonstrates in a striking manner the completeness of recovery that may be obtained in cases of severe collapse under anaesthesia when the appropriate treatment is used in time.

Medical Memoranda

Parturition with Fractured Femur

The following case, in which the Roger Anderson method of treating fractured femur was applied to facilitate delivery, seems to be worthy of record.

CASE REPORT

The patient, a normally developed woman aged 27, sustained a simple transverse fracture of the shaft of the right femur in the upper middle third on March 21, 1941. She was treated at first by skeletal traction on a Thomas splint. This overcame the shortening and angulation, but it was found impossible to correct by manipulation a posterior displacement of the distal fragment by nearly one diameter. There was very slow formation of callus. Open operation with onlay bone graft was performed on June 23, when soft-tissue interposition was found responsible for the difficulty in reduction and the delay in union. After this, immobilization in a plaster spica was continued for three months. The patient had had no menstrual period since Jan. 27, and when the plaster was removed she was obviously pregnant. After a period of exercises in bed she was allowed to walk in a calliper, union appearing satisfactory, but she unfortunately refractured the callus and graft shortly afterwards. On Nov. 6 the femur was immobilized by the Roger Anderson half-pin technique, using two half-pins above and two below the fracture, and incorporating the superior and inferior half-pin units in a plaster from groin to knee. This was very comfortable, and the patient was able to sit in a chair.

At this stage she was transferred to the maternity department, and was discovered to have a breech presentation with extended legs which could not be turned by external version. It was decided to let her go into labour, and to perform Caesarean section if there was any difficulty. The foetus was known to be small and the pelvis roomy.

On Dec. 3 she went into labour spontaneously by rupture of the membranes at 10 a.m. Pains began 6 hours later, and the breech was seen at the vulva two hours after that. Delivery was carried out in the lithotomy position, the injured leg being held by a nurse. In this position there was no difference from the delivery of a normal patient. The child was a healthy male of 5¼ lb. The puerperium was uneventful.

COMMENT

It would seem that the Roger Anderson method is extremely satisfactory in this complication of parturition, and in fact the only one which gives an absolutely free hand to the obstetrician. There is no reason why delivery should not be carried out in the lateral position if preferred, provided the leg in plaster is uppermost and is suitably held.

With the Roger Anderson apparatus not available, Mr. Norman Capener has recently suggested, and has successfully used, 6-in. carpenters' gimlets instead of the half-pin units. Two gimlets are inserted into the upper fragment so that they lie in two planes and engage in the opposite cortex of the bone. The lower fragment is held by one gimlet and a transfixing Steinmann pin at the lower end. These are all incorporated in plaster from the groin to just above the knee. This method gives a somewhat more bulky plaster; but there is absolute fixation of the fragments, and it has proved very successful.

I am indebted to Mr. Norman Capener for permission to publish the case, and to Mr A. L. Candler for allowing me to deal with the obstetric side.

G. BLUNDELL JONES, M.B., B.S.,
Resident Surgical Officer, Royal Devon and Exeter Hospital

Treatment of Plantar Warts

In common with the experience of observers elsewhere I have been struck by the increased number of children coming to my orthopaedic clinic in Rochdale with plantar warts. The treatment of these has in the past been very troublesome and rather unsatisfactory. The opinion has been hardening that these warts are due to an infective agent, the exact nature of which has not been ascertained. Having seen the good results obtained in the treatment of impetigo by covering the patches with elastoplast and leaving the plaster undisturbed for a week or more, I determined to try a similar treatment for these warts. As the infecting agent must be a much less virulent one than in the case of impetigo, I argued that the elastoplast must be left undisturbed for a much longer period in order to get the same effect. I accordingly began to treat plantar warts by covering them with elastoplast. The results have been uniformly good.

Since March, 1940, 17 cases have been seen; of these, 9 have been completely cured (for details, see Table) and 8 later cases are still under treatment. I have used the ordinary 2-in. elastoplast for the feet and 1-in. elastoplast for the toes. Wherever possible the elastoplast has been put right round the foot or toe and overlapped a little, as that makes the bandage more secure. The elastoplast is left undisturbed for at least 3 weeks (longer if possible), and the patients are instructed to keep the bandage dry and when a bath is being taken to keep the foot out of water. At the end of 3 weeks the bandage is removed, the foot cleansed with methylated ether, and a new bandage put on. This treatment is continued until the skin is normal. Quick results must not be expected, but in not one case have we failed to effect a cure.

	Sex	Age (years)	Position of Warts	No. of Applications	Duration of Treatment	Result
1	M	8	Heel of lt. foot, base of rt. gt. toe	4	9 weeks	Cured
2	F	11	Lt. heel	5	12 ,,	,,
3	M	13	Lt. heel, rt. heel, base of rt. gt. toe ..	6	14 ,,	,,
4	F	12	Base of rt. gt. toe ..	7	21 ,,	,,
5	F	13	Under right metatarsal heads	6	14 ,,	,,
6	M	13	Both heels ..	4	13 ,,	,,
7	F	11	Multiple warts under rt. heel	4	11 ,,	,,
8	F	11	Between 1st and 2nd toes rt. foot; on sole under lt. metatarsal heads	7	17 ,,	,,
9	M	9	Sole of lt. foot ..	4	13 ,,	,,

My impression is that the longer the elastoplast can be kept dry and left undisturbed the more rapid is the cure. This is confirmed in one or two of the cases in which holidays have intervened and patients have waited an extra week before coming for treatment. Every treatment is carried out at the clinic, and the patients are instructed not on any account to disturb the plaster. Each case is seen 2 to 3 weeks after the treatment is completed to make sure that there is no recurrence.

The treatment is carried out for me by my physiotherapist, Mrs. Fletcher, to whom I am indebted for her care both in the details of the treatment and in the keeping of records.

W. HIRST BATEMAN, M.B., Ch.B.

At the annual general meeting of the National Birthday Trust Fund the chairman, Sir Julien Cahn, reported that the Trust continued to maintain the headquarters at 57, Lower Belgrave Street, providing accommodation for the Queen's Institute of District Nursing and the College of Midwives. The Analgesics Appeal Fund had supplied 50 machines for administration of gas-and-air analgesia free of charge to hospitals and district nursing associations, etc., and 46 at a nominal charge of £5, 36 of them to district nursing associations. The Fund had also supplied 48 machines to emergency maternity hospitals, under a scheme approved by the Ministry of Health, at purely nominal cost to the local authorities concerned. Sir Julien also referred to the report upon the nutrition work of the National Birthday Trust Fund and Joint Committee of Midwives which Dr. Margaret Balfour would shortly complete, and to the Human Milk Bureau at Queen Charlotte's Hospital, a further activity of the Fund.

Reviews

GENETICS AND RACE BIOLOGY

Race, Reason and Rubbish. An Examination of the Biological Credentials of the Nazi Creed. By Gunnar Dahlberg, M.D., LL.D. Translated from the Swedish by Lancelot Hogben, F.R.S. (Pp. 240. 8s. 6d.) London: George Allen and Unwin.

The writings of Prof. Dahlberg are nothing if not robust. To anyone who likes his popular science served up without subtlety in the manner of the traditional sergeant-major this book should make a strong appeal. If, however, the fastidious avoid it altogether because of its ridiculous title, or abandon it after glancing at its earlier pages with their unattractive illustrations, they will be depriving themselves of one of the best and clearest of recent popularizations of genetics and race biology. The account of the principles of heredity is thoroughly plain and forceful, but the most skilful feat of exposition is the explanation in very simple language of the genetics of populations. This is, of course, the field in which Prof. Dahlberg has himself done so much important work. Much emphasis is naturally attached to his own conception of "isolates," which some prefer to treat under the more general headings of inbreeding and assortative mating. The fact that a few generations ago the choice of a mate by a human being was usually effectively limited to a relatively small group of persons, and the further fact that the average size of these isolates has greatly increased in recent times, have very significant consequences. To give a single example, Prof. Dahlberg advances an interesting speculation as to the increase in stature which has occurred in Western Europe in recent times. Thus, in Sweden the average height of recruits for military service has increased by 9 cm. during the course of a century. It is usual to ascribe this to improved standards of living, but, he points out, it is difficult to accept so simple a view, because the increase has been uniform whereas the improvement in standards of life was much more marked during the second half of the period; moreover, the famine years of the 'sixties were without effect on the figures. The increase might possibly be due, however, to continuous increase in the average size of isolates, provided that genes increasing stature tended more often to be dominant than recessive.

The subject of race is dealt with as trenchantly as the rest, and if few in this country are to-day in need of conversion, many will be glad to read such a lucid exposure of the myths which have had so harmful an effect in Germany. Occasionally, however, the arguments of the author appear tendentious. His contention that the effects of large-scale sterilization would be negligible is based on the assumption of the recessive transmission of undesirable characters; he does not consider the much more probable case of multifactorial inheritance with or without partial dominance. He minimizes the effects of differential fertility by concentrating all his arguments upon social classes and ignoring the undoubtedly large association between intelligence and infertility quite apart from questions of social class. Nevertheless, in spite of the imperfections which it displays so honestly upon its face, this able book deserves recommendation.

WOUND TREATMENT IN THE LAST WAR

Pathology and Treatment of War Wounds. Researches from the Inoculation Department, St. Mary's Hospital. By Sir Almroth E. Wright, M.D., F.R.S. (Pp. 208. 21s.) London: William Heinemann, Medical Books, Ltd.

This volume is a reprint in book form of ten papers published by Sir Almroth Wright during or shortly after the war of 1914-18. Two of these deal with gas gangrene, one with the acidosis of shock, and one with the phenomenon of "intertraction"; the remainder expound general principles of wound treatment with a view to combating sepsis, and describe the many ingenious forms of experiment on which the author's doctrines are based. A proposition fundamental to all this work is made on p. 8: here it is said of Metchnikoff's experiments on phagocytosis that because they were made *in vivo* they were made "under conditions which cannot be sufficiently simplified to give quite unambiguous answers. And we require for the elucidation of our problems, and for all detail work connected therewith, absolutely simple crucial experiments, such as can only be made *in vitro*." Whether these experiments, using perhaps a capillary tube and a drop of blood or serum and some bacteria, do in fact wholly reveal the processes at work in a wound in the living body may be questioned: the conditions may be simplified, but they are also in many ways different. That observations made in this way can altogether take the place of experiment in the living animal, or that their results are more significant, will not be generally accepted.

Much has happened since these papers were written, and of the principles they advocate some are still accepted and others have been superseded. The value of early excision and the futility of crude antiseptic applications need no emphasis nowadays, but antiseptics have come into their own again with local sulphonamide chemotherapy, and users of the Bunyan bag would not now accept even the strictures on hypochlorite treatment which it receives here. Hypertonic saline may perhaps have suffered undue neglect, as may the use of vaccines in persistent wound infection. We are grateful for this volume not so much for the lessons to be learned from it a quarter of a century after most of it was written as for the complete picture it gives of a historic controversy. As an exposition of a system of experiment and belief it would have been better rewritten, since as it stands there is naturally much repetition, and even illustrations recur, but we should then perhaps lose some of the vigorous and picturesque language of which the author is a master. As an exercise in polemics the last chapter is unrivalled: to tear one's opponent into little shreds with such magnificent freedom of expression must be highly satisfying, and is perhaps worthy of emulation in these too-polite times.

A STUDY OF THE BLOOD IN CANCER

A Study of the Blood in Cancer, with Special Reference to the Needs of the Tumour Clinic. By O. Cameron Gruner, M.D. (Pp. 100. 15s.) Montreal: Renouf Publishing Company; London: H. K. Lewis.

This book is a plea for the value to be obtained from detailed examination of the blood in the diagnosis of cancer. It is well produced, at a reasonable price, by subsidy from the Archibald Cancer Research Fund of McGill University, Montreal. Methods comprise studies of wet preparations, vitally stained preparations and ordinary blood smears, as well as certain special techniques. Observations are made in very great detail of all the cellular and plasmatic elements in the blood, using ordinary illumination, dark ground, polarized light, and ultra-violet light. The code for mononuclear cells of the blood alone contains 80 different possibilities. The possible data are so numerous that they can only be expressed as pictorial diagrams, patterns, or trends. There are unsuspected pitfalls, too, as in the demonstration that a meal which features pork will produce a blood picture indistinguishable from that of cancer, though of course normality reappears after eight or nine hours.

The author does not claim absolute certainty of diagnosis by these methods, but he does indicate a very high degree of probability. It would seem as though the degree of alteration of the blood picture is proportional to the degree of advancement of the disease. These results may interest people who are interested in the natural history of the blood or in the curious bypaths of cancer research. We doubt whether they have any value for the early diagnosis or treatment of cancer. It is evident that the author has a high "credulity index." The most remarkable expression of this is his opinion that in radi-aesthesia, a procedure akin to water-divining, we have "an absolute test (100% both ways) for the existence of malignant disease in the body." This suggests that radi-aesthesia can even make the distinction between cancer and pork. It is remarkable that claims to diagnose cancer infallibly should be made without any corroboration by experimental observations or statistical data.

BROMPTON REPORTS

Brompton Hospital Reports. A Collection of Papers recently published from the Hospital. Volume X, 1941. (Pp. 127. 5s. 7d., post free.) Copies obtainable from the Secretary of the Hospital, London, S.W.3.

A further collection of papers from the Brompton Hospital recently published in medical journals forms the tenth volume of the *Reports*. In fact one paper, on the persistence of lipiodol in the lungs after bronchography, has not previously appeared. F. H. Young and E. Gantz indicate the practical importance of the problems involved, and review past experimental work on this subject. Their own contribution is based, in the first instance, on pathological examination of lungs or lobes removed at operation from patients in whom bronchography had been carried out at some time or other before the operation. The duration of the retention of the oil appeared to depend on two factors: on the cellular activity of the phagocytes and on the speed with which fibrous tissue is developing. Experiments were carried out to determine whether decomposition of the oil took place under physical conditions that develop when the iodized oil is retained in the lungs—that is, exposed to air and moisture. No free iodine was detected, but some dissociation of the oil did occur, as was shown by the rise in acid value. Further experiments showed that, while the oil was not an adequate medium for bacterial culture, the addition of broth to it did provide a medium in which the bacterial growth was not inhibited by the oil. Thus infected material, if present, was probably conveyed by the oil to the terminal bronchi and alveoli. These investigations are being continued, and further results should be awaited with interest.

The papers previously published include three of particular interest in wartime: on drainage of the pleura, by R. C. Brock; on closed wounds of the chest, by J. G. Scadding; and on traumatic haemothorax, by C. Hoyle. There are also reprinted A. F. Foster-Carter's valuable paper on bronchial adenoma from the *Quarterly Journal of Medicine*, and some notes on the treatment of carcinoma of the bronchus with radon seeds by F. C. Ormerod.

Notes on Books

Part I of the *Fourth Supplement to the British Pharmaceutical Codex, 1934*, has been published by the Council of the Pharmaceutical Society by the Pharmaceutical Press, 17 Bloomsbury Square, W.C.1, at 4s. 6d. It contains amendments to the monographs in Parts I and II, amendments to some formulae in Part III, and amendments to appendices in Part IV.

Mr. **Nils L. Eckhoff** has completely revised the text of *Aids to Osteology* for its fourth edition and has introduced forty-two diagrammatic line drawings of bones to help the student in revision. As in the third edition, the nomenclature recommended by the Anatomical Society of Great Britain and Ireland is used throughout. This little book is one of Baillière, Tindall and Cox's Students' Aids Series and the price is 6s.

Dr. **Gordon Sears** has revised his *Vade Mecum of Medical Treatment* for a third edition (Edward Arnold and Co., 10s. 6d.), and it continues to give in a convenient form an outline of the treatment of the diseases most commonly met in general medical practice. References to chemotherapy have been brought up to date, the term "sulphonamide" being used for the whole group of drugs. Practical notes on the three main types—sulphanilamide, sulphapyridine, and sulphathiazole—are included in an appendix.

Preparations and Appliances

A LIGHT TRAILER AMBULANCE

Lieut.-Colonel J. L. Moir, M.B., Medical Officer, No. I Zone, Anglesey Home Guard, writes:

At my request Mr. Duerr of Bodorgan, a well-known inventor, undertook the designing of a light trailer ambulance, especially suitable for the use of the Home Guard in country districts. The chief features I asked him to incorporate were as follows: easily man-handled and towable by any light car; cheap and easy to produce in quantity; designed to exclude so far as possible the exhaust gases of the towing car; easily loaded and handled by two persons; some method of heating provided, and if possible provision for an attendant to travel in contact with the stretcher occupants. Mr. Duerr made a complete model to scale, and the following brief specification shows how well these ideals have been attained.

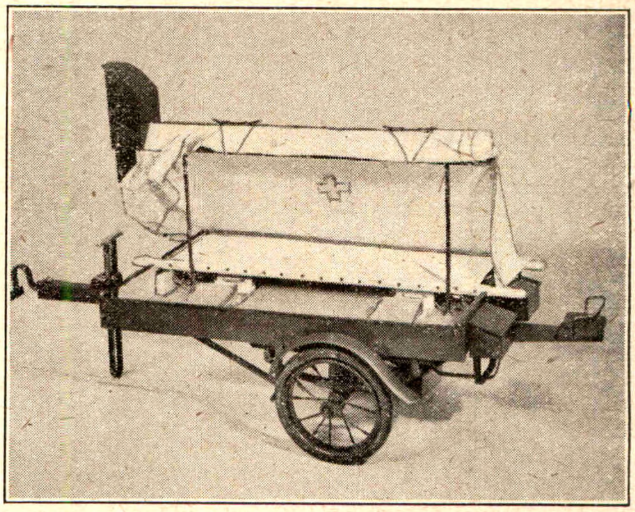
Ventilation and Heating.—Fresh air is drawn in at the highest point through a chute or cowl. It is conducted along the ridge of the ambulance and distributed through a series of holes to the interior to avoid strong draughts, thus creating a slight internal pressure which leaks out at the various small openings around the stretcher tray and prevents the admittance of exhaust fumes. Provision is made in the tray for four hot-water cans, two under each stretcher, holding about a gallon each.

Loading.—It is safe to say that two girls of ordinary physique can easily lift a loaded stretcher and place it into position without strain, because the top of the tray is only 30 inches off the ground and there is no sliding in from the rear to be done; all that is necessary is to lift the stretcher, step sideways, and lower into slots.

Brakes and Springing.—Owing to the extreme lightness of the ambulance, only parking brakes are necessary; these automatically come into operation when the leg of the towing beam is lowered and, acting directly on the tyres, they are most efficient. Very light and supple leaf springs are provided for the comfort of the occupants and are made fairly flat.

Wheels, Tyres, and Cover.—Motor-cycle type wire wheels with 26″ × 2½″ tyres are suggested. Any suitable canvas anti-gas or other cover may be used, fastened down by press studs and held up by cords and cleats.

Towing Attachment.—The object in providing the simple attachment shown on the model is to enable any local blacksmith to fit the swan-neck fitting to any car, either to the car frame or bumper bar. (One of the many more elaborate ball joints could be used instead.)



Attendant's Seat.—When it is desirable that the attendant should be in contact with the stretcher cases, a pillion seat is provided with foot rests under the tray. Contact is made by means of the "lightning fastener" down the centre of the canvas cover immediately in front of the attendant, the occupant's head being next to him. A bell communicating with the driver is available to the attendant and to the patients. An interior light run off a dry battery is to be fitted under the ridge board. Two sloping-lid first-aid boxes are fitted into the rear end of the ambulance within easy reach of the attendant. (A motor-cycle spring pillion seat, three or four inches deep and fitted with a back rest, could be used in place of the plain seat shown on the model. Two small windows might with advantage be fitted into the rear end of the canvas cover, to keep the occupants under continual observation.)

The photograph (by Jones-Owen of Bangor) shows the canvas cover lifted from one side with one stretcher in place; the other has been removed to show the two hot-water cans under each stretcher.

The main features of this "Duerr-Moir" ambulance are: (1) its extreme lightness and simplicity; (2) it can be used either as a trailer ambulance attached to any light car or as a hand ambulance detached from a car, to be used over fields and rough ground; (3) the simplicity of the heating and ventilating systems; (4) it is cheap to produce in large quantities; (5) the cost of upkeep is practically *nil*.

Comment or criticism is invited and the opinion of medical men practising in country districts would be especially welcomed.

That the use of metrazol in the treatment of psychoses may be the origin of spontaneous epileptic seizures in a patient not previously subject to them is the conclusion of E. Liebert (*J. Amer. med. Ass.*, 1942, **118**, 119). In 8 of his patients epileptic convulsions developed 3 to 24 months after the cessation of metrazol treatment. As these patients had been observed in hospital for many years, it was not difficult to establish the fact that this was a new phenomenon, and as, in addition, epilepsy is rare in cases of schizophrenia, Liebert believes that in his cases the seizures were the result of the treatment to which the patients had been subjected.

BRITISH MEDICAL JOURNAL

LONDON

SATURDAY AUGUST 8 1942

SPHINCTER MECHANISM OF THE BILE DUCT

In the second part of his Hunterian Lecture published in our present issue Rear-Admiral Gordon-Taylor discusses the important question of the sphincter mechanism of the bile duct and raises many problems of great interest. Oddi's original investigations were carried out in 1887 and were based upon both anatomical and microscopical work, mainly in animals. Since that time the sphincter to which his name is given has been the object of varied and elaborate study and experimentation. Anatomists have demonstrated beyond question that a definite intrinsic sphincter exists at the terminal portion of the common bile duct, and Gordon-Taylor's review concludes that the muscle sheath of the duct is derived from the circular muscle coat of the duodenum. It will be remembered that the common bile duct runs obliquely for a distance of one or two centimetres through the duodenal wall in company with the pancreatic duct (of Wirsung), the two uniting at the ampulla of Vater into a common papilla projecting into the duodenum. In this passage through the duodenal wall the ducts are subject to extrinsic muscle influences, and constriction of the common duct may be brought about by this intestinal muscle—from which the intrinsic muscle of the sphincter is itself derived. Gordon-Taylor points out that the direction and arrangement of the fibres around and in the duct wall also enable them to act by retracting the papilla and partly by drawing together the duodenal villous processes, thereby preventing the outlet of bile into the intestine. Embryological and comparative anatomical researches also tend to confirm this conclusion—namely, that the sphincter mechanism of the ampulla is derived from the muscular coats of the duodenum and not from any distinct circular muscle of the duct itself. Whatever the exact origin, however, of this sphincter muscle, there can be little doubt as to its importance and its special functions in biliary control. The exact extent of nervous and hormonal control is uncertain, but that some reciprocal mechanism exists whereby gall-bladder contraction is related to sphincter relaxation is undoubted. If the sphincter mechanism is destroyed or put out of action the gall-bladder does not fill and bile flows directly into the intestine, so that one important function would appear to be that of aiding gall-bladder filling as well as regulating the flow of bile into the intestine. As Gordon-Taylor remarks, the ascending hepatic infections which may so often follow surgical interference with the normal bile-duct structure indicate another of its important functions—namely, the prevention of regurgitation of duodenal contents into the common bile duct.

Although experimental work involving incision and intubation of the bile duct is open to criticism, many reports of such investigations are available, and Bergh, reviewing this subject recently, confirms certain main points upon which agreement is fairly general. A fatty meal, for example, causes relaxation of the sphincter, while magnesium sulphate does the same with less regularity but with definite gall-bladder contraction. Morphine causes contraction of the sphincter—under the conditions of the investigations—while the presence of a stone causes irritability and tendency to spasm which may persist many weeks after its removal from the common bile duct. Such irritability and spasm may also be of significance in conditions other than biliary calculus. Ivy and others demonstrated in 1933 that painful sensations identical with biliary colic might be caused by spastic contraction of the sphincter of Oddi in man; and Westphal, Gleichmann, and Mann in their important book in 1931 described in detail various forms of dyskinesia of the gall-bladder. As long ago, however, as 1761 Morgagni had suspected that spasm of the bile duct might produce clinical disorders, and Oddi himself supported this proposition. We are still, however, uncertain of the true frequency of such "functional" gall-bladder conditions or of the exact details of the nervous control of the biliary apparatus. Mirizzi has attempted to investigate this subject by the slow injection, at operation, of 3 to 5 c.cm. of iodized poppy-seed oil into the cystic duct of man, followed by immediate radiography. He concludes, after some 800 examinations by this method, that increased sphincter spasm associated with and caused by a calculus leads to anatomical changes of biliary stagnation and muscular hypertrophy at the sphincter of Oddi. Cases of purely functional dystonia of the sphincter may also, in his opinion, show dilatation of the biliary tree, and in these cases reflux of lipiodol into the duct of Wirsung is a characteristic radiographic finding; this he suggests is due to an active (abnormal) biliary current and is not a purely passive phenomenon, and it is thus a condition of possibly high significance in the causation of pancreatitis.

How far variations in activity of the sphincter of Oddi in fact occur in health and disease it is difficult to say. Fatty meals may cause relaxation, but fresh olive oil may have no such effect, and similarly a carbohydrate meal exerts little influence (Bergh). To what extent its action is reflexly affected by the stomach, colon, or other distant organs is also uncertain. It seems clear, however, if only from the careful study of structure reported by Gordon-Taylor, that the regulation of biliary flow into the intestine—and hence of much of the digestive activities—must depend upon a delicately controlled intrinsic bile duct sphincter; it is thus not simply governed by the movements of the duodenal wall which allow bile to flow according to whether they are relaxed or contracting.

POST-WAR EPIDEMIC PROBLEMS

Dr. Melville D. Mackenzie, in common with many who were brought into close contact with the great human tragedy arising from the uncontrolled prevalence of epidemic disease, destitution, and famine in the years following the last war, has evidently given much thought to the medical and public health problems that are likely to call for urgent solution in Europe when fighting ceases. The results of his cogitations are published by the Royal Institute of International Affairs in a pamphlet entitled *Medical Relief in Europe: Questions for Immediate Study.*[1] He writes of some of the grim happenings in those post-war years as seen by himself, evidently in Russia; of some of the difficulties encountered by philanthropic organizations and Governmental agencies in providing adequate relief; of the lack of co-ordination of the many agencies engaged in the stupendous task of trying to control the spread of disease in the conditions then prevailing and of the loss of efficiency occasioned thereby; and of typhus fever, malaria, and malnutrition. He describes the remarkable development of international health work during the twenty years between the two world wars and makes suggestions regarding the resumption of that work after this one. The machinery for post-war medical relief is outlined.

---

[1] Chatham House, 10, St. James's Square, London, S.W.1 (2s.)

Some of Dr. Mackenzie's statements and contentions may not command universal approval, but all will agree as to the necessity for setting up co-ordinating medical machinery before the war ends, so that no time may be lost in dealing with the most urgent problems that will arise. Dr. Mackenzie reminds us that during the three years following the last war more people died from famine and preventable disease than were killed in the war. It should not be forgotten that a still greater mortality was caused by the pandemic of so-called influenza that was ravaging the world when the Armistice was signed. That murderous pandemic flared up almost simultaneously in most parts of the world. Countries very remote from the scenes of actual fighting suffered most. Individuals in the prime of life paid a heavier toll than infants and the aged. Public health effort to control its spread proved lamentably inefficient. Reference is made to those happenings because they explain in part the fact that valuable time was lost in mobilizing international aid for the newly created States of Eastern Europe in their fight with devastating epidemics, chiefly typhus fever, the legacy of the war. It was influenza that occupied the attention of most public health administrations of the world during the winter of 1918-19 almost to the exclusion of all else: it was influenza that was the subject of the first post-war international medical conference, in Paris in March, 1919. Small wonder: no such epidemic had occurred within the memory of living man, and we were all sadly conscious of the limitations of preventive medicine in the face of such a catastrophe.

Dr. Mackenzie makes no reference to the work of the Typhus Commission, subsequently called the Epidemic Commission, of the League of Nations. That Commission was set up with the express purpose of co-ordinating international work in the post-war epidemic campaign, about which he has much to say. The Commission's contribution to the fight was by no means insignificant: it may claim to have done all that was humanly possible within the limits of the not inconsiderable sums that were placed at its disposal. The difficulties it encountered and the experience it gained might perhaps be turned to good account in making plans to cope with similar situations that are likely to arise when present hostilities cease. It is true that the Epidemic Commission, created in 1920 (there was then no Health Organization of the League of Nations), did not start field work till 1921. This delay was in one sense fortunate: the renewal of hostilities between Soviet Russia and Poland would have destroyed much of the first work it was planned to do had an earlier start been made.

Fortunately, in public health, as in other fields of human endeavour, events rarely justify one's worst forebodings. Forecasts of epidemic happenings are frequently wide of the mark. It would be foolish, however, to shut one's eyes to the probability of catastrophic happenings in the field of public health when hostilities cease. Dr. Mackenzie is concerned only with likely happenings in Europe. The possibilities in other parts of the world are perhaps even more disquieting. In the Far East plague, cholera, and small-pox, to name but three dread scourges, may well give rise to very serious trouble when normal commercial relationships are re-established. Malaria in many countries has only been kept under control by unceasing vigilance and effort; the relaxation of that control may have incalculable consequences. There can be no doubt about the need to set up co-ordinating international medical machinery before the war ends: the combined medical resources of the world may well be taxed. The growth of international medical work in the inter-war period simplifies considerably the approach to the problems confronting us. The Epidemiological Intelligence Service of the League of Nations continues to function in Geneva. Its *Weekly Epidemiological Record* still appears regularly: the amount of information this contains in present conditions is no small achievement. The machinery, experience, and contacts of the Health Organization of the League of Nations should prove of very great value in facing post-war epidemic problems.

INTESTINAL ANTISEPSIS

Sulphaguanidine, although introduced for the main purpose of treating bacillary dysentery, has also been used to reduce the bacterial population of the lower bowel as a safeguard before operations on the colon. Another drug has now been introduced for this purpose, and remarkable claims are made for it by E. J. Poth and F. L. Knotts.[1] Succinylsulphathiazole behaves like sulphaguanidine in being poorly absorbed from the alimentary tract; indeed only 5% of the amount administered appears in the urine. It is hence not surprising that full doses can be given without any untoward general effects. A high concentration of the drug thus persists in the intestinal contents, and is believed to exert its bacteriostatic action not directly—since succinylsulphathiazole has almost no *in vitro* action on bacteria—but by liberating sulphathiazole. That hydrolysis of the drug does occur in faeces can be shown by maintaining voided specimens at body temperature; in these the concentration of free sulphathiazole steadily rises. Whatever their exact mechanism, the effects reported are astonishing. In a patient "prepared" with succinylsulphathiazole the bowel at operation is found to be collapsed, the evolution of gas having ceased. It is possible in the dog so treated to cut through one-third of the circumference of the descending colon and, leaving it unsutured, to close the abdomen, without causing fatal peritonitis. The stools are "relatively odourless" and the numbers of living *Bact. coli* per gramme of moist faeces usually fall from 10,000,000 to less than 1,000. No other micro-organism was studied quantitatively; that anaerobes must be affected is deduced merely from the change in character of the intestinal contents, and *Strep. faecalis, Bact. aerogenes,* and *Proteus* are said to be resistant to the drug. It is also mentioned that dysentery bacilli are susceptible and typhoid and paratyphoid bacilli resistant. The effect on various elements in the normal flora of the lower bowel is clearly a matter calling for further study, and such a study is said to be in progress. Although it is not really known which of the numerous species found in the bowel can play an active part in producing peritonitis, it is incredible that the escape of intestinal contents should be rendered harmless merely by reducing its *Bact. coli* content. The bacteriostatic effect as indicated by this reduction was regularly achieved except in a few cases having either diarrhoea or obstinate constipation; either of these conditions, the former particularly, prevents the proper action of the drug. These authors have now treated with it 100 patients suffering from various specified bowel conditions; they record its effects only in 27 cases requiring operation on the lower bowel, in which its administration was designed to prevent post-operative peritonitis. Of these, 10 are described in detail and 4 are illustrated by diagrams of the complex resections and anastomoses which were necessary. Operations inevitably soiling the peritoneum were performed with apparent impunity, and freedom from post-operative distension was a further advantage secured. This form of medication will evidently become a necessary adjunct to colonic surgery, and succinylsulphathiazole appears from this account to be the drug of choice, but a close comparison of its effects with those to be obtained with sulphaguanidine, preferably by quantitative bacteriological methods, would establish its position more clearly.

PROGNOSIS OF ACUTE HAEMORRHAGIC NEPHRITIS IN CHILDHOOD

Varying opinions on the ultimate outlook for children who have suffered from acute haemorrhagic nephritis have been expressed in the past twenty years. These discrepancies appear to depend essentially on the standards offered by the investigators, and the introduction of the "Addis count" some years ago was an attempt to reach agreement on what could be regarded as normal. This test turns upon examination of the deposit obtained after high-speed centrifugalization of the urine, and various workers have set out the upper limits for the calculated numbers of casts, white epithelial cells, and red blood cells after a drop of the deposit has been examined in a blood-counting chamber. G. E. Pittinos, J. D. Craig, and A. G. DeSanctis[1] report the use of this Addis count among other methods in the examination of 32 patients who had all suffered from acute haemorrhagic nephritis at an average time of about six years before the investigation, only 4 of the patients having had the acute illness less than two years before being examined. The group of 19 boys and 13 girls were subjected to the following procedure: physical examination; blood-pressure determination; analysis of the urine with an Addis count; complete blood count; chemical blood examination for urea, non-protein nitrogen, creatinine, cholesterol, serum albumin, and serum globulin; and a urea clearance test. All the children were found to be essentially normal physically, except one who had a raised blood pressure with no other abnormalities. Routine examination of the urine showed 6 children with albuminuria. Two of these were found to have high white cell counts by the Addis method, which were ascribed to pyuria rather than to nephritis, one showing an abnormal renal pelvis with an intravenous pyelogram. Two others with albuminuria were examined eight and ten months later and found to be normal. One patient had no abnormality apart from the albuminuria, and had two normal Addis counts eight months apart. The authors do not think that this patient should be classified as having residual kidney damage of what is termed "latent nephritis" type. The remaining patient with albuminuria did not return for further study and was therefore classified as having potential latent nephritis. Chemical examinations of the blood for retention of nitrogenous products were all negative. Urea clearance tests on all patients were normal, and there was no anaemia ascribable to the nephritis. Addis counts done on all the children were normal except for the two who were considered to have pyuria. These results would indicate that acute haemorrhagic nephritis in children has an excellent prognosis, for the Addis count introduces strict criteria of cure. The 32 patients who formed the subjects of this investigation were, however, drawn from 110 patients suffering from acute haemorrhagic nephritis in the Post-Graduate Hospital, New York, in the years 1928-39. Four patients died during the initial manifestations of their disease, and the attempt to establish contact with the remaining patients produced only the 32 who served for this follow-up study. The value of the report lies, therefore, not so much in any statistical deductions as to the ultimate prognosis in this disease as in the emphasis laid upon the need for standardizing the criteria of a healed kidney. It is suggested that every child who has suffered from acute haemorrhagic nephritis should be examined every three months up to and including two years after the acute attack. This examination should include physical overhaul, blood-pressure reading, and examination of the urine, and an Addis count at the end of two years. If in the course of the two-year period the slightest urinary abnormality is found the Addis count should be employed as a further check.

SIMMONDS'S DISEASE

Wasting and loss of strength are such important symptoms that the study of their rarer organic causes is of special interest. In this connexion Simmonds's disease is of particular significance because it brings into prominence the endocrine factors in cachexia and offers some key to the complex interaction of the ductless glands. First described by Simmonds in 1914, panhypopituitarism, or Simmonds's cachexia, has since received its fair share of attention in medical literature. It occurs most often in women between 30 and 40 years of age and in those who have borne several children. In some cases the condition follows infection or trauma, and in others it arises after severe post-partum haemorrhage. The disease usually begins with amenorrhoea, and wasting appears later, in some cases being very slight. Although loss of strength and alertness are the main symptoms, the hypogonadism and general lowering of metabolism, with loss of hair and retardation of growth, are characteristic. Most cases are fatal, but the course is slow, and the gradual wasting may in time lead to extreme emaciation. The cause of this disease is some destructive lesion of the anterior pituitary.

Non-fatal and minor degrees of the condition are difficult, if not impossible, to distinguish with certainty from other causes of wasting and weakness. Of these the one which has perhaps given rise to most difficulty is anorexia nervosa. Here the wasting is often extreme, though the weakness is much less in evidence. Indeed the typical patient with anorexia nervosa, usually a girl of from 15 to 25 years of age, may appear full of energy and be constantly on the go, while losing weight to an alarming extent as the weeks pass. In anorexia nervosa the periods also cease, blood pressure and basal metabolism fall, and the hair may be lost. In pituitary cachexia the patient wants to eat but cannot, whilst in anorexia nervosa the sufferer —often emotional or actually psychopathic—usually "wants" to lose weight and will not eat; in both conditions there is often found an undue sensitivity to insulin with a relatively low blood-sugar content. In a recent paper R. Fraser and P. Smith[1] have investigated the insulin sensitivity by means of an insulin-tolerance test, as well as the urinary excretion of steroids derived from the adrenal cortex and testis, in a number of cases of Simmonds's disease and similar clinical conditions. Though of necessity post-mortem confirmation of the diagnosis was not possible and the number of cases was small, the results suggest that by these tests a distinction between the various conditions may be made biochemically. Briefly put, the insulin-tolerance tests showed that the initial fall in blood sugar after insulin injection was followed, in cases of Simmonds's disease, by a longer delay in return to the previous fasting level than in normal individuals. In 3 out of 8 cases of anorexia, however, a similar delay, or "hypoglycaemic unresponsiveness," was also found, so this response is not confined to panhypopituitarism. The authors found that in all their cases of Simmonds's disease except one the urinary 17-ketosteroid assays were negative, while in the 4 cases of anorexia tested the assays varied from 2.7 to 14.7 mg. per 24 hours. Such investigations as these offer hope that further knowledge may be derived from the subtle reactions of the pituitary upon growth, the sex glands, and the adrenals; they also suggest methods of diagnostic value to the clinician.

BLOOD FLOW TO LIMB MUSCLES

Studying by means of a segment plethysmograph the flow of blood to the muscles of the forearm and calf, Wilkins and Eichna[1] observed that warming the body led to an increased, and cooling to a decreased, flow. Stimuli known to cause vasoconstriction in the hands and feet had to be more intense to produce measurable changes in the forearm and calf. Immersion of the hand or foot in iced water was the most effective of such stimuli. On the other hand, certain emotional stimuli—such as mental arithmetic—which are known to cause vasoconstriction in the hands and feet resulted in an increased flow of blood to the forearm and calf. This reaction was of two types—early and delayed. All the reactions mentioned, except the delayed vasodilator response to certain emotional stimulation, depended upon an intact sympathetic nervous supply. There is evidence of a humoral mechanism, possibly adrenaline, in this reaction. Vasodilatation in the forearm and calf, due to exercise or after temporary arterial occlusion (reactive hyperaemia), was unaffected by sympathectomy. It was also shown that vasodilatation after arterial occlusion for five minutes was relatively complete, being unaffected by sympathectomy, warming the body, and by other stimuli known to cause vasodilatation. As this method is technically easy and its effect relatively complete, the authors recommend it for inducing experimental vasodilatation in the forearm and calf. The only thing which materially affected the degree of vasodilatation was a strong vasoconstrictor stimulus; weak vasoconstrictor stimuli had no effect. The flow of blood during reactive hyperaemia varied directly with the blood pressure, both in normal subjects and in hypertensives. Further, if the blood pressure of normal subjects was raised to levels comparable to that of the hypertensives, the flow of blood was of the same order in both groups. Conversely, when the blood pressure of hypertensives was lowered to normal levels the blood flow was like that in normal subjects. The authors think this is evidence against the view that in hypertensive subjects the vessels in the limbs are in a state of increased peripheral resistance which cannot be affected by physiological vasodilatation. Five patients with hyperthyroidism were also investigated. All showed an increased blood flow to forearm and calf, both under basal conditions and with reactive hyperaemia. There was little correlation between the volume flow and the basal metabolic rate.

While there is little exactly new in these observations, and although the method of measuring the blood flow to the muscles of the forearm and calf is not ideal, the work nevertheless represents a step in the right direction, and has an important bearing on the interpretation of the clinical tests usually employed in cases of peripheral vascular disease. Surgeons have long mistrusted predictions, based on skin-temperature reactions, that sympathectomy would be without benefit in certain cases of intermittent claudication. There has always been a need for measurement of blood flow to the muscles rather than to the skin, and this should heighten the value of preliminary testing.

CONFIDENTIAL DEATH CERTIFICATION

Civil registration has been carried out in the Province of Quebec since 1622. When the Province joined the Canadian registration area in vital statistics in 1925, no change was made in the civil registration system, and the collection of vital statistics was entrusted to the clergy. The old system, which was not designed for vital statistics, had defects when judged by modern requirements. The procedure regarding death registration was somewhat cumbersome. The undertaker was responsible for obtaining the death certificate, and he retained it until the interment, when he delivered it to the priest or minister, who made his returns at the end of the month. By this procedure the certificate was seen by a number of persons, and in a small community the disease from which a person died soon became known to all. This practice embarrassed the doctor who wanted to maintain his professional secret and yet desired to provide accurate information to the Ministry of Health as to the cause of death. In 1931 a number of physicians who had visited Europe suggested that the procedure should be modified by adopting the European system of a confidential medical certificate. The term "European system" is hardly accurate, because confidential death certification was not common in Europe, although it was established in Switzerland. The need for some modification in registration was emphasized in 1936-7, when an investigation was carried out on death certification. The inquiry covered 5,965 deaths, and visits were made to the doctor issuing the death certificate, and he was asked his actual opinion regarding each case, without reference to the statement he made on the official certificate. This inquiry revealed that 1,163 certificates, one-fifth of the whole, had been intentionally falsified, 322 were partially inaccurate, and 841 were completely untrue. The concealment of four causes of death comprised almost 90% of the false certificates: they were cancer 23.9%, heart diseases 22.5%, infectious diseases 20.7%, and tuberculosis 11.8%.

The situation was remedied in 1940 by adopting a system of confidential medical certificates.[1] The new certificate has a flap which covers the medical certificate proper and is sealed. Anyone opening the flap is liable to prosecution. On the face of the flap, which is a permit for burial, it is noted whether death was due to violence or infectious disease, so that the Public Health Acts dealing with these causes can be complied with. No conclusions regarding the possible alterations in the trend of the death rates can be attempted after so short a trial, but there has been an increase in some causes of death which in the past were the ones most often concealed. Besides the satisfaction that the new certificate has given the medical profession, the statements provide more explicit details and are easier to interpret and tabulate. One disadvantage is that the mucilage on the flap tends to stick and has given rise to loss of certificates: the author states that "in our office we have lost a few thousands." In view of this defect it seems that the death rate from specific causes must still be inaccurate, although an improvement has been obtained in proportional mortality.

Doubtless the innovation has improved the vital statistics of Quebec, but to the perhaps conservative Briton the method has no advantage over ours, and it does not seem likely that such a scheme would improve our vital statistics. Our control of local registration is more efficient than in Quebec, which is "on the somewhat benevolent basis of co-operation." The knowledge of one's family medical history is surely not generally undesirable, and for most life insurance policies it is a necessity if a penalty is to be avoided.

MAINLY ABOUT WOMEN*

BY

Sir ALFRED WEBB-JOHNSON, K.C.V.O., C.B.E., D.S.O., T.D.

President of the Royal College of Surgeons of England; Surgeon to the Middlesex Hospital

It is always a pleasure to me to visit the London School of Medicine for Women, for I have the greatest admiration for your achievements, and I have many personal links with members of your staff—past and present. Whenever I visit you I feel I am treading historical ground, for, though medical women are now such an essential part of our profession, that position has been attained only by the self-sacrificing efforts of your founders and the devoted determination of those who fought their way to general acceptance.

In the Apocrypha it is written: "Oh ye men, are not women strong?" Although this fact has been realized from such early times, and is borne in on us forcibly to-day, it is but yesterday that the rights of women have been recognized. Great women there have been throughout known history—great Queens—and some other words of the Apocrypha are applicable to them as well as to men: "Leaders of the people by their counsels, and by their knowledge of learning meet for the people, wise and eloquent in their instructions: all these were honoured in their generations, and were the glory of their times."

Seeds Sown in the 18th Century

I always think that the seeds of the general recognition of woman's true place in society were sown in the latter half of the eighteenth century, about the time that "gentlemen" were invented by George III and Beau Brummel made bathing fashionable. My mind naturally dwells much on this period, for it was the time of the foundation of scientific surgery. It was an age of intellectual giants—the time of Samuel Johnson; of Zoffany, Hogarth, Reynolds, and Gainsborough; of Burke, the elder and younger Pitt, and Gibbon; of Nelson and Cook; of Sheridan and David Garrick—it was the time of John and William Hunter and Edward Jenner. In this starry firmament a group of women of the period shone as a brilliant constellation.

Not unnaturally women found their earliest opportunities for distinction in the giving of pleasure, especially in the imitative and creative arts. There were great players like Mrs. Cibber, Peg Woffington, and Mrs. Siddons. Among the painters of the time a woman, Angelica Kauffmann, was one of the first of the Royal Academicians. But, to my mind, the brightest star was Fanny Burney. She vindicated the right of her sex to an equal share in the fair and noble province of letters. But though generally acclaimed, Fanny Burney still felt the disabilities of her sex. Her father's lack of interest was largely responsible for her selling the copyright of *Evelina* for £20. Her father's estimate of her worth was probably only typical of the general attitude towards women, and he thought he was doing her good service when he secured for her an appointment as lady-in-waiting to an exacting Queen, although it was clear that in that position she would have no time for writing. Johnson's estimate was probably coloured by a subconscious superiority complex, for he influenced her writing and ruined it. I am also drawn to Fanny Burney because she provides a slender link with surgery. Her patronymic was originally McBurney, a name familiar to you all; and she was a visitor at Hunter's house.

It was natural that women should find in the field of social reform their opportunity to take a larger part in the life of the community. The outstanding pioneer was Elizabeth Fry. Though she was the mother of eleven she found time to fight for and attain shelters for the homeless, and libraries for naval hospitals; and she was able to carry through her great work of prison reform and to bring about the foundation of charity organization societies. From Elizabeth Fry it was but a step to Florence Nightingale, and then to women's fight to enter the medical profession. The women's movement took full shape in the middle of the nineteenth century. Medical women and Florence Nightingale, as a great historian has said, did more than any others of their sex to bring about the new conception of the place of women in society, and to carry to a successful issue the movement for the general emancipation of women. Voices had been raised before. But it is not the one who first says a thing, but those who say it so long, so loudly, and so clearly that men are compelled to hear them—it is to them that the credit belongs.

In the fight for women's rights there have been mistakes, but, after all, as Milton said, error is but opinion in the making. Nothing great was ever achieved without enthusiasm, but too much attempted often leads to violent reaction. The history of the movement provides a striking example of the inevitable gradualness of change, and shows that besides a moving power there is also need for a steadying power. Improvement is then gradual and slow—but sure and lasting: "*Chi va piano va sano ed va lontano.*" No martyrdom has changed the known tendency of things. An era comes to an end. Time advances, facts accumulate, doubts arise, and conditions become ripe for a new epoch. The spirit of the age then makes straight the path of progress.

Times had changed now, for improvements in travel had made it possible for women to move more freely about the country. Before railways all but the wealthy had to "stay put." Boarding schools and visits to friends became commoner after railway travel was possible. The horizon was enlarged and possibilities of freedom and service were seen more clearly.

Two Pioneer Medical Women

The pioneers in women's fight to enter the medical profession in this country were Elizabeth Garrett and Sophia Jex-Blake. After a long struggle Elizabeth Garrett attained her personal ambition, and soon showed that a woman could be a reliable physician. I am glad to recall that, although my hospital does not admit women students, Elizabeth Garrett found some of her difficulties met by being allowed to attend classes at Middlesex. She used her feminine arts to get her way. And, why not? As a pretty girl once said to Max Beerbohm: "After all, women are a sex by themselves, so to speak." The assistance Elizabeth Garrett received at Middlesex was chequered and intermittent; but in spite of disappointments her debt to Middlesex and the medical staff was great, and, on the whole, she had happy memories of the hospital and always said that the training was invaluable to her. And so Elizabeth Garrett reached the *Medical Register*.

Sophia Jex-Blake was of a different type. She was determined to force the padlocked portals of the medical schools, and, when in the United States, was not prepared to graduate from a women's college. She failed to enter Harvard, however, in spite of the powerful support of Oliver Wendell Holmes and Brown-Séquard, and decided to seek medical education in her native land. She tried London and Cambridge without success, and then concentrated her attack on Edinburgh. Through strife, riot, and public protests she eventually attained her goal.

Elizabeth Garrett was an instance of an individual success, but Sophia Jex-Blake fought the battle not for herself alone but for all, and events moved rapidly. In 1874 your School was founded, largely owing to the efforts of Miss Jex-Blake. Two years later a new Medical Act allowed examining bodies to admit women, and in 1877 the Royal Free Hospital was secured for the clinical teaching of your students. London University opened its doors to women, and they lost no time in showing their worth: your brilliant alumna Mary Scharlieb passed her examinations in the first division, and was awarded gold medals and a scholarship. Women doctors had arrived. Throughout the struggle there was a good deal of mental confusion and many hard words. These, I hope, have been softened by the passage of time.

Women and the College of Surgeons

I come to you to-day, dressed in a little brief authority, representing a College which was slow to take advantage of the Medical Act of 1876; for it was not until 33 years later that our diplomas were granted to women. But, though the doors were slow to open, women have not been slow to enter, and now one in eleven of our Members and one in eighty of our Fellows are women.

---

* Address at the London School of Medicine for Women, on the occasion of the presentation of prizes, July 24, 1942.

Women did not attain full rights in the College until the reign of George V, when the Charter of 1926 was applied for during the Presidency of my late friend and colleague Sir John Bland-Sutton. As the next Middlesex surgeon to be elected to this high office, it was my privilege to be the first President to welcome women Fellows and Members to the Buckston Browne Festival, the occasion being honoured by the attendance of our only lady Honorary Fellow, H.R.H. the Princess Royal.

The Charter of 1926 was a landmark in our history because it gave women Fellows the same privileges as men Fellows. They are now able to vote for the election of Members of Council; they may themselves be candidates for the Council, and they are eligible as Examiners, and for the offices of President and Vice-President.

Our College has good reason to be proud of its women Fellows and Members. Two of them have held Hunterian Professorships; one has been Arris and Gale Lecturer, and one has been awarded the John Hunter Medal and Triennial Prize. In addition, two women students have won the Hallett Prize in the Primary Fellowship, and three have won the Begley Studentship.

My personal links with women surgeons have been very happy ones. I was proud to call Dame Mary Scharlieb my friend. I am also proud to be Vice-President of the Marie Curie Hospital, to the excellent work of which I was glad to call attention in the Bradshaw Lecture on "Pride and Prejudice in the Treatment of Cancer." In the last war I took over the Château Mauriciens in Boulogne base from Louisa Garrett-Anderson and Flora Murray. Curiously enough, I turned it into a hospital for women, while they came home and founded a hospital for men—the hospital of splendid memory in Endell Street.

War seems to give women their greatest opportunities for proving their worth. Florence Nightingale found her opportunity in wartime. War again in 1914 brought a big opportunity, and maturity may be said to have been thrust upon you almost at the sword's point or the cannon's mouth. In this war you took an honoured place by acknowledged right.

The Future of Women in Medicine

And, now, what of the future? You are heirs to a great inheritance. Your place is assured though special lines of work may be reserved for you. In India, for example, there is still a special field of work for women. In the Simon Report we read: "The women's movement in India holds the key to progress, and the results it may achieve are incalculably great. It is not too much to say that India cannot reach the position to which she aspires in the world until her women play their due part as educated citizens."

In social medicine women can play a special part in working for what it is fashionable to call "positive health." In the Scriptures it is written: "They that are whole need not a physician, but they that are sick." Those who hold that view to-day are in a small minority, for members of the medical profession no longer regard themselves merely as agents in the recognition and treatment of diseases; they now want to know the cause of disease and how to prevent it. The sick and injured cannot be herded through "marshalling yards" as some organizers would have us believe. The family doctor will remain the backbone of medical practice. As Alexis Carrel emphasized: "Disease is a personal event. It consists of the individual himself. The patient is not limited by his outer covering. His surface is not his real frontier. A man may be more interested in his environment than in his own body. His position in the community, for example, may appear to be of more importance than life itself." Medicine is essentially a calling. It has been well said that a physician [illegible] surgeon may possess the science of Harvey or Hunter and the art of Sydenham and yet be lacking in those finer qualities of heart and head which count for so much in a profession so intimately linked with the humanities.

Many of you may be about to leave hospital. There you have seen the best that medical science has to give. I often recall what Sir Frederick Treves said to King Edward VII when his Sovereign thanked him for his life-saving attentions. Having in mind the splendid work of his great hospital—the London—he replied: "Sir, you have had as much care and skill in your illness as the humblest of your subjects."

I congratulate the prize-winners and venture on a few words of advice. Don't hurry out into full independent autonomous isolated work: knowledge and timber should not be much used until they are seasoned. Remember that your calling is an exacting one: to do your duty you must be well equipped; for, as Kipling said when speaking in the Royal College of Surgeons, "Is it any wonder that your calling should exact the utmost that man can give—full knowledge, exquisite judgment, and skill in the highest, to be put forth, not at any self-chosen moment, but daily at the need of others?" Remember also Francis Bacon's words: "I hold every man a debtor to his profession; for the which as men of course do seek to receive countenance and profit, so ought they of duty to endeavour themselves by way of amends to be a help and ornament thereunto." In spite of a busy life and hourly calls you must keep up to date and thus help to narrow the gap between experiment and practice—between the acquirement and application of new knowledge. In the war against disease, just as in military campaigns, a time lag may be fatal to success.

We are now all of one great army, concerned no longer with the place of women or the preserves of men, but with the practice of medicine and the war against disease. As members of a united profession we should bear in mind what Tennyson wrote in *The Princess*:

> "The woman's cause is man's: they rise or
> sink
> Together."

BEIT MEMORIAL FELLOWSHIPS

At a recent meeting of the Trustees of the Beit Memorial Fellowships for Medical Research Dr. A. N. Drury, F.R.S., was appointed to the Advisory Board in the place of Prof. A. J. Clark, F.R.S., whose untimely death in July, 1941, was so deeply regretted by all who had worked with him. The Trustees noted with pleasure the election this year of three past Fellows to the Fellowship of the Royal Society—namely, E. Hindle (Junior Fellow 1910–12 and Senior in Tropical Medicine 1927–33), F. M. Burnet (1926–7), and A. R. Todd (1935–6). Out of the 28 present Fellows there are now 14 seconded for whole-time war work.

The following elections were made, with permission for each Fellow to be seconded at any time for war duties:

Fourth Year Fellowship (£500 a year)—E. G. L. Bywaters, M.B., B.S.Lond. To continue his studies of crush injuries in relation to kidney function, at the British Postgraduate Medical School, London.

Junior Fellowships (£400 a year).—D. Herbert, M.A., Ph.D.Camb. To study the biochemistry of toxoids for active immunization against gas gangrene, at the Dun Biochemical Laboratory, Cambridge University. F. W Landgrebe, D.Sc.Aberd. To study the separation of posterior pituitary hormones and their clinical uses, at the Medical School, Aberdeen University.

The Maternity and Child Welfare Group of the Society of Medical Officers of Health, in a memorandum on planning for the future health services for mothers and children, points out that factors outside medicine influence maternity and child health, and therefore the provision of adequate food, housing, and financial aid are essential features of any satisfactory plans. A complete maternity and child welfare service—with ancillary services—should be available to all as part of a national salaried medical service organized on a regional basis, with the Health Centre as the local unit. The prevention and treatment of illness in children should be in the hands of doctors who have had a special postgraduate experience, and the present maternity and child welfare and school medical services should be amalgamated, so that one service provides for the child from birth to school-leaving age. There should be enough institutional accommodation for all women who require or prefer confinement in maternity hospitals, which should be separate units of general hospitals. The obstetric care and confinement of the mother should be carried out by a specialist obstetric service based on the maternity hospitals. For ante-natal purposes a minimum of 10 hospital beds per 1,000 persons in an area is required, in addition to hostel accommodation, which should be attached to maternity institutions, especially those serving rural areas. There should be short-period residential nurseries for children during the mother's "incapacity." The Group also recommended the organized teaching of "parentcraft" during adolescence.

Reports of Societies

TREATMENT OF MALARIA

At a meeting of the Royal Society of Tropical Medicine and Hygiene on July 23 Sir **RICKARD CHRISTOPHERS**, the president, gave a paper on the treatment of malaria, a subject, he said, of the greater importance because British troops are already operating in many malarious countries, and the indications are that sooner or later others will be added.

Nowadays, with powerful specific drugs, malaria was looked upon as a relatively mild disease, but in the absence of these drugs it would be seen again in its old grim shape, with infections whose fatal course the physician was unable to stop. The sheet-anchor was the specific drug, which up to ten years ago was quinine only. The cultivation of cinchona bark had unfortunately been concentrated in Java, and with Java now lost to the Allies the supply of quinine must be seriously curtailed. It was doubtful whether other cinchona alkaloids or various derivatives of the quinine type, such as hydroquinine, were available to meet what must now be an enormous demand for efficient substitutes, and it was necessary to turn to recently developed synthetic antimalarial drugs.

The first antimalarial compound ever to be produced was plasmochin, synthesized in 1924-6, and this was followed in 1932 by atebrin, probably the most powerful antimalarial at present known. Since then many compounds had been made in different countries, all more or less closely related to or identical with atebrin or plasmochin; thus quinacrine, acriquine, and mepacrine were respectively French, Russian, and British atebrin, and praequine, plasmocide, and pamaquin the corresponding equivalents of plasmochin. It was stated that biologically mepacrine, the British product, was indistinguishable from atebrin, and it seemed a pity to have changed the name.

Plasmochin could not be considered a satisfactory substitute for quinine in the treatment of the acute disease, nor, by itself, in the after-treatment or prophylaxis, but atebrin had come to be generally accepted as equally effective with quinine. With atebrin not more than 0.3 g. in the day was given, in three doses of 0.1 g. The toxicity did not seem to be great, but atebrin showed quite definitely some cumulative effect, and therefore the daily total was fairly well fixed. Usually in the acute attack atebrin was given for a period not exceeding 7 days, and if necessary repeated again after an interval. In prophylaxis the chief difference from quinine was in the avoidance of continued daily administration; this again was on account of the cumulative effect. Usually the dosage was rather cautious, say 0.2 g. on two successive days in the week or even at longer intervals. Atebrin was a powerful yellow dye, and its administration was liable to give rise to yellow coloration of the skin, but this was in no way related to jaundice and it had no disadvantage except the cosmetic one. It was supposed that atebrin did not, like quinine, precipitate blackwater, but it was perhaps early to be completely sure on that point.

One feature in which atebrin had a clear advantage over quinine was its suitability for intramuscular injection. The treatment of the ordinary case of malaria was best carried out by oral administration, but should there be any sign of cerebral or other pernicious manifestations parenteral administration was a matter of urgency. The intramuscular use of quinine in such circumstances was quite unjustified, as the necessary rapid absorption could not be expected. Intramuscular injection was in fact not so much used in pernicious malaria as in the treatment of cases of a chronic kind thought to be resistant. Actually the use of intramuscular quinine for such a purpose was largely the perquisite of the doctor babu or low-class practitioner, and in the opinion of many it amounted to malpractice. The results at best formed a necrotic mass in the tissues and at the worst led to tetanus or serious sloughing and other evils. With atebrin, however, it appeared to be accepted as the correct procedure, and Sir Rickard explained that the difference was due to the different hydrolysis—the splitting up of a proportion of the salt into the base and "free" acid—of the two drugs. With atebrin the hydrolysis was negligible, so that the sloughing of the tissues after injection was not experienced to anything like the degree that it was with quinine. He added that it was improbable that the last word in synthetic antimalarials had been said. Certain arsenical compounds had been shown to have a sterilizing effect on certain forms of malaria. Sulphonamide preparations might yet prove useful, and a compound of the synthalin type had also been found effective.

Dr. **WILLIAM HUGHES** of Lagos followed with a short note on the treatment of malaria in a hyperendemic zone. In the treatment of troops in such an area, he said, antilarval methods were out of the question. He would recommend nothing beyond the mosquito net and the maintenance dose of quinine, just as with the civilian. He favoured 5 grains daily as the routine treatment and 30 grains during the acute stage.

Prof. **WARRINGTON YORKE** said that in losing Java we had lost 90% or more of the world's supply of quinine, and if increasing numbers of our troops were operating in malarious countries and more and more of our ships calling at malarious ports, there would be a great demand for an adequate supply of the only practical substitute for quinine—namely, atebrin (or mepacrine)—and the conservation of the limited supplies of quinine remaining. If quinine was to be saved the economy must be in the large amounts used for prophylactic treatment. Prof. Yorke added that he had listened with surprise and consternation to the president's denunciation of the intramuscular use of quinine. When the president said that it was unjustifiable to treat serious cases with pernicious manifestations by means of intramuscular quinine because the necessary rapid absorption could not be expected, he parted company from him. He had found that one or two intramuscular injections of quinine bihydrochloride were invaluable, only it was urgently necessary to make certain that the patient would absorb some quinine very quickly. He agreed that it was by no means all absorbed, but enough was absorbed to produce the desired effect. He had never seen the terrifying results the president had depicted.

Major **ROWLAND HILL** said that under-treatment was the greatest fault in the present-day management of subtertian malaria in hyperendemic zones. Of atebrin he said that it was as non-toxic as any drug could be expected to be. He at least had never seen any toxic response. As an anti-relapse drug atebrin was far more satisfactory than quinine, and something between 4 and 7 standard-size tablets a week were helpful in preventing recrudescence.

Sir **PHILIP MANSON-BAHR** said that he believed quinine and atebrin went well together in subtertian malaria, but he could not agree that the intramuscular or intravenous administration of atebrin was anything like as efficacious as the same administrations of quinine.

Nova et Vetera

CLOSED TREATMENT OF FRACTURES

Dr. Robt. D. Campbell (Kirriemuir) writes:

I see that this question has arisen again—in the article by Dr. J. Trueta (May 16, p. 616). An experience of mine might, perhaps, take the paternity of this technique a little further back. In December, 1901, I was acting as "locum" in a district of the Island of Lewis. One day I received a message to go to a case of a broken leg. This involved a journey by land and sea-loch, occupying the greater part of the day; finishing with a climb up a hill-face in the dark to one of the "black" houses of that time. The patient was a boy of about 14. The leg, from knee to ankle, was enclosed in a thick casing, evidently composed largely of peat pulp. On breaking this off, there was the usual wound in the front, about the middle of the lower leg, where the sharp end of the fractured tibia had penetrated and then been retracted. The fracture was in a very good position. There had been a good deal of leakage, but this had been well absorbed by the peat casing. After spending the night at a shooting lodge, I took him by sea next day to Stornoway. The eeriness of the situation, the dim light and the peat reek, with the unwashed look of the people and the undertones of the Gaelic, made me ask myself if what we were witnessing was not the survival of a surgical procedure which might have come down even from Palaeolithic times. I wondered sometimes what would have happened to the leg if it had been left alone.

Correspondence

Social Medicine

SIR,—As a member of our local group committee, I have been much interested in the various discussions on this subject and also in the letters in your *Journal*. It seems to me that there is a confusion of ideas, especially among the consultants Surely the preventive side of medicine—such as housing, employment, diet, wages, sanitation, heredity, environment, etc.—is the concern of the M.O.H.s and the Ministry of Health. It is quite useless telling the busy general practitioner that he is to prevent his patients getting ill and to diagnose their complaints before they have any physical signs. The fact remains that they come to him ill, and he has to deal with them on the spot and help them immediately. It matters not if the doctor is a panel doctor, a paid State doctor, or a private doctor; his success will depend on his ability to deal with his patients clinically (of course Prof. Ryle is right to use this expression).

I personally don't think it matters a row of pins, from the patients' point of view, what type of practice the future scheme is made of. What does matter is that the members of our profession shall be the right type of man and woman, keen on medicine, with a good training, and, if possible, with compulsory house jobs and postgraduate work: and, may I add, with as little clerical work as possible.—I am, etc.,

Hampstead HAROLD VAN PRAAGH.

The Planning Commission's Report

SIR,—May I offer the following opinions on the Planning Commission's interim report?

1. The Commission is to be congratulated on its achievement.

2. The majority view (paras. 47, 48, 49), envisaging the suggested reorganization in hospital, consultant, public health, and other services and standard form of health centre, is well reasoned, sound, and acceptable.

3. A whole-time salaried medical service would be wholly bad for the profession and the public. It bristles with unpalatable features and would "flatten" two essential points in any good medical service: (*a*) the individual general practitioner's independence in medical (and other) thought; and (*b*) the spur to achievement given the practitioner by the knowledge that legitimate rewards—humanitarian, professional, financial—are only his in direct proportion to his efficiency and endeavour.

4. There is no need for a whole-time service (or for the third, half-and-half, scheme). All its good points, and much more besides, are encompassed by the scheme outlined in the majority view.

5. Many of the advocates of a whole-time State service seem intolerant when not dogmatic or fanatical. Obviously good points against whole-time service, such as free choice of doctor and bureaucratic stultification, cannot be dismissed as "bogies" or "resuscitated platitudes." With gentler thought it can be realized that the community, "who want a complete medical service" (Dr. A. R. Fox, July 11, p. 53), will get a complete service in the scheme envisaged in the majority view—a scheme in which the profession loses little or nothing, gains a lot, and is spared a great deal. "No one can be so short-sighted as to imagine that the end of the whole scheme will not be a whole-time salaried medical service. . . . Let us have something new: it has to come anyway" (Dr. G. G. Airey, July 11, p. 52). What is to be gleaned from these and similar statements? Such obsessed authors should realize that there is nothing inevitable about a whole-time salaried service; on the contrary, many of us have found that the majority of our colleagues view it with disfavour if not with abhorrence. They might also consider the letter by the serving officer in the *Supplement* of July 18 (p. 6), which drops an authoritative hint on what a State service can be like, and advances a plea "which I am sure will be echoed by the great majority of doctors who, like me, are temporarily with the Forces, to put on the brake, strongly, and stop this precipitous rush towards State medicine." The lay press teems with evidence of the extravagance and inadequacy of State control, and of the frustration forced on the individual by what the late Lord Chief Justice Hewart called "the new tyranny"—bureaucracy.

6. Dr. T. D. Culbert's belief (July 18, p. 79) that "since a capitation fee is retained the major evil of the present panel scheme is retained—namely, the inability of the doctor to act justly, according to his lights, towards his patient for fear of offending him and losing financially by a transfer"—cannot be supported when one reads in the report (para. 69) that the capitation fee is but one of the three parts of which a doctor's remuneration would consist, and that another would be a basic salary.

7. In 13 years of general practice in all manner of communities I have frequently deplored the present system, but nevertheless feel convinced that State medicine would be a most unhappy blunder, and would indeed point the lack of "the necessary will and the necessary perseverance." To a G.P. the majority-view proposals seem almost too good to be true, giving maximum benefit and minimum tears to patient and doctor, with one notable exception.

8. As Dr. Culbert's letter notes: "Close liaison between the general practitioner and the hospital is not envisaged nor is the need for it stressed enough." Here is a real deficiency, and this deeply important point forms the subject of the admirable article by Mr. Staveley Gough and Dr. Duffus (*Supplement*, July 18, p. 5), which should be read by all interested as a most constructive complement to the Commission's report. We recognize that the medical efficiency of any scheme rests on the efficiency of the family doctor. Create the "general practitioner hospital unit"—i.e., set aside hospital wards for the treatment of cases by general practitioners, with the freedom for the latter to seek specialist help when necessary, as at any other time—then would many patients be given an additional very real benefit; the G.P. would be afforded continuity of treatment, and G.P. prestige and standard would be raised.—I am, etc.,

Englefield Green, Surrey N. MORTIMER VALLELY.

Use of the Term "Orthopaedic"

SIR,—In suggesting that orthopaedic surgeons should confine their activities to "the treatment of deformities" Brigadier Max Page (July 18, p. 79) is approaching the subject from the point of view of a surgeon who finds part of the orthopaedic field attractive, and would like to put up a fence on the far side of it to keep the orthopaedic surgeon out! If, however, we approach the subject from the interests of the patient and of the general practitioner, it is clear that there is great advantage in giving the orthopaedic surgeon free access to treat injuries of bones and joints, and the opportunity of teaching pre- and post-graduate students in this field.

Sir Robert Jones said, when delivering the Lady Jones Lecture on crippling due to fractures before the University of Liverpool in May, 1925[1]:

> "It will, I think, be generally agreed that the teaching of the proper treatment of fractures can only be effective when based on experience, not of mechanical detail alone, but also of the principles which relate to deformity. Every fracture should be looked upon as a potential deformity. Some of these deformities develop in very insidious ways. They may be traced to omissions or commissions, or both. They may arise during treatment or when treatment is discarded. The least obvious frequently prove the most disabling
> The surgeon called upon to teach should possess the experience enabling him to visualize all such difficulties and dangers which are sure to encompass the practitioner in after-years.
>
> "Team work and segregation in many fields of surgical endeavour saved the lives of patients and the reputation of surgery. This became evident in fractures more than in any other branch of work. I have no hesitation in saying that greater progress was made in the treatment of fractures during the four years of war than had occurred during a generation in our big teaching hospitals.
>
> ". . . there is no mind so comprehensive that it can keep pace with all the requirements of modern surgery."

These are the carefully chosen words of a great surgeon, a very wise, considerate, and open-hearted man. It is surely right that there should be team work among surgeons. Some should confine themselves to the study and the treatment of the ills and accidents of the locomotor system. These men become more and more expert in the treatment of fractures.

---

[1] *British Medical Journal*, May 16, 1925

Could anything be more illogical than an attempt to exclude a surgeon from the treatment of fractures because he has given up abdominal surgery!

The training and experience of an orthopaedic surgeon involve close study of the biology and reactions of the locomotor system. These possess characteristic differences from those of the viscera. These two systems differ widely in their function in reaction to injury and inflammation, in the methods which will restore function, and in the relative speed (or lack of speed) in their response. There is a difference, too, in that after a well-chosen and well-executed operation on the viscera the surgeon's work is often largely done, whereas the locomotor system commonly demands long and watchful rehabilitation. The good orthopaedic surgeon must combine the mechanical aptitude and craftsmanship of the engineer with the understanding, the gentleness, and the patience which living tissues need.

So to limit the field of orthopaedic surgery that it would fail to attract young men of first-class ability would be disastrous for all those crippled or threatened with physical disablement; for *unless orthopaedic surgery is very good it is very little good!* Well knowing this, Sir Robert Jones,[2] having outlined the orthopaedic field much as it is now widely accepted, says:

> "This definition admittedly covers a large area of surgery, and for this reason will attract the very best of our young surgeons. These are the men whom we specially desire to attract in order that they may devote themselves to a very intricate branch of work, bristling with problems which require solution, and demanding the highest operative skill."

To the orthopaedic surgeon a difficult fracture is a fascinating problem, to most other surgeons a confounded nuisance! Max Page is indeed an exception; he has given proof of his continued interest in orthopaedic work and has been welcome. His present attitude is unlike him, and his proposal is indefensible.—I am, etc.,

Oxford. G. R. GIRDLESTONE.

SIR,—It would appear that Brigadier Max Page in pleading for a more restricted use of the term "orthopaedic" has changed his views. On Oct. 1, 1935, when he gave his presidential address before the Section of Orthopaedics of the Royal Society of Medicine (*Proc. roy. Soc. Med.*, **29**, 63) he said, "Orthopaedics has so expanded that it may now *properly* be considered as that section of general surgery which deals with *any* disorder of the locomotor system." (Italics mine.) I cannot get up much enthusiasm about these definitions, but if we must have one then I am quite prepared to subscribe to Brigadier Page's. His letter gives one the impression that what he really fears is that the orthopaedic surgeons are using the term "orthopaedics" in such a way as to deny to surgeons who are not so labelled the right to treat disorders of the locomotor system. There is ample evidence that this is not so; two examples will suffice: Mr. Hey Groves has been President of the British Orthopaedic Association, Mr. Max Page President of the Orthopaedic Section of the R.S.M.—I am, etc.,

Oxford. H. J. SEDDON.

SIR,—Brigadier Max Page states that according to the O.E.D. the word "orthopaedic" became current in this country about 1840. The term really began to make its way with the founding of the Royal Orthopaedic Hospital in Bloomsbury Square in that year. The founder of the hospital was W. J. Little, a physician to the London Hospital, who has been regarded as the father of orthopaedic surgery in England. He performed the first tenotomy for the cure of deformity in London in 1837, and some years later described spastic paraplegia in infants, a disease to which his name was subsequently attached. But the originator of the word "orthopaedic" was Nicholas André, professor of medicine of the Royal College in Paris. In 1741 he published a work in two volumes entitled *Orthopaedia; or, The Art of Correcting and Preventing Deformities in Children*, which was translated into English. André coined the term from two Greek words, "orthos," which signifies straight, free from deformity, and "paedion," a child. His own comment was, "Out of these two words I have compounded that of orthopaedia to express in one term the design I propose, which is to teach the different methods of preventing and correcting the deformities of children."

On strict etymological grounds the word "orthopaedia" was sufficiently expressive to convey what André implied, but in actual practice the choice was not particularly happy, for there was perpetual confusion in many minds as to the meaning of the word. Apart from the general public, members of the profession with some Latin and less Greek readily assumed that it meant to make the foot straight and no more. But gradually that misconception largely disappeared. Again, in the process of time, like so many other words, "orthopaedic" has expanded its meaning so that it embraces the surgery of bones, joints, and muscles. It is surprising to be told that in America the scope of orthopaedic surgery is in dispute. That country is about the most progressive in this branch of surgery, and a perusal of the *Journal of Bone and Joint Surgery*, a significant title of the official periodical of the two great American orthopaedic societies, should leave no doubt about the meaning of the term to transatlantic orthopaedic surgeons.

Brigadier Max Page fears that if the term "orthopaedic" is to include injuries and diseases of the locomotor system, then their treatment will be restricted to orthopaedic surgeons. That would not be so. For any surgeon who has had the necessary training should be able to engage in this work whether he be a general or an orthopaedic surgeon. But if, as he suggests, the term should be restricted to the treatment of deformities, then there would be a real danger of the orthopaedic surgeon finding himself confined to the cure of deformity. No orthopaedic surgeon that I know would accept such a retrograde conception of his work. The fault is not with the orthopaedic surgeon but with the choosing of a term at once restrictive in its root meaning and expecting it to stand for a branch of surgery more expansive than an eighteenth century physician could possibly have dreamt about or intended. There are many branches of surgery, and some have emerged in our own day—e.g., thoracic surgery and neurosurgery. They are a tribute to the progress of surgery and they are special, requiring a training and a technique of their own. If we are to avoid looseness of nomenclature we must first begin by asking: "What is general surgery"?—I am, etc.,

London, W.1. ARTHUR ROCYN JONES.

Complacency in Anaesthetics?

SIR,—In a leading article (July 18, p. 73) you refer to the prevailing interest in anaesthesia and to the correspondence to which it so frequently gives rise. A 29-years experience in teaching students and the administration of a general anaesthetic on more than 20,000 occasions cannot but result in the forming of some definite impressions and opinions which may be of some interest and possibly of some value to others Briefly they may be stated as follows:

1. The administration of anaesthetics is an art. Idiosyncrasy to the drugs which we employ is common and a measured dosage system is not successful.

2. A drug can be introduced directly into the circulation to produce an *uncontrollable* state of coma, but this procedure does not appear to be a desirable one, nor does it call for the exercise of the art of the anaesthetist.

3. When complete relaxation of the abdominal muscles is required a deep anaesthesia *without cyanosis* must be obtained. For this purpose a potent anaesthetic agent is required. The best we have is ether. There are degrees of deep anaesthesia, and these can only be recognized if the administrator has a full view of the patient's face and eyes. Complete control over his jaw and upper respiratory passages is also necessary. A closely fitting face-piece is thus undesirable. The mask and drop-bottle form the ideal method for these cases, the mask being something more than a "rag" and the bottle being one that will deliver a steady drop at any desired rate.

4. Machines are of great use for operations requiring a lighter type of anaesthesia, and a machine of some kind is absolutely necessary when remote control of the anaesthesia is required.

5. Ether convulsions are not mentioned in Hewitt's *Anaesthetics and their Administration* (1912) or in Buxton's *Anaesthetics* (1941). Their occurrence dates from the intro-

---

[2] Cameron Lecture on "The Necessity of Orthopaedic Training," delivered at the University of Edinburgh, Jan 14, 1921 *British Medical Journal*, Feb. 5, 1921

duction and general use of machines, and the attempt by means of these machines to give gas–oxygen–ether when a deep anaesthesia is required. Convulsions are a terminal symptom in asphyxia and probably due to oxygen starvation of the brain cells. Cyanosis is not a true indication of the degree of anoxaemia present, and anoxaemia may exist in the case of an anaemic patient without obvious cyanosis. Abdominal relaxation cannot be obtained with a weak anaesthetic agent without producing a degree of anoxaemia, and this condition persisting may give rise to convulsions. Do administrators always remember that their patient requires at least 250 to 300 c.cm. of oxygen per minute? Under no circumstances should a patient be deprived of his full supply of oxygen. I have never seen a case of ether convulsions.

6. Since entirely discarding chloroform in 1916 *as an agent for the induction of full anaesthesia,* I have had no anaesthetic deaths. Grave emergencies rarely occur, and it is many years since I had occasion to perform artificial respiration.

A death rate on the table of between 1.3 and 1.8 per 1,000; or a record such as that described by Mr. Hamilton Bailey, accepted with complacency, must, in the minds of many of us, give rise to a sense of wonder.—I am, etc.,

Dundee. ARTHUR MILLS.

Anaesthetic Death in the Surgery

SIR,—The following experience in a general practitioner's consulting room will, I feel sure, be interesting to your readers.

A girl aged 8 years was brought into my surgery one night about two months ago with a severe supracondylar fracture of the right humerus. As the nearest hospital was over 7 miles away, and the shock produced in sending her there was taken into consideration, I decided to reduce the fracture in my surgery. I accordingly administered an ether–chloroform mixture (3 to 1), open mask method, and with the assistance of a nurse, to whom I handed the mask after the child was apparently under, I reduced the fracture. This had barely been done when my attention was called to the child. She had stopped breathing and was practically pulseless. I promptly began artificial respiration for about one minute, then told the nurse to carry on while I went to open a cupboard for the purpose of giving an injection. This delay took about 1½ minutes. I injected 2 c.cm. anacardone into the right deltoid, then again took over the artificial respiration from the nurse. After half a minute I gave this up and decided to massage the heart. I dug my left hand under the costal cartilages and placed my right hand over the praecordium and did a cardiac massage for a quarter of a minute. The sense of relief when the child took her first breath can be imagined.

It would be interesting to know what the consensus of opinion is with regard to general practitioners accepting a responsibility of this type, which seemed justified in the circumstances. Death in a surgery and death in a hospital under these conditions are regarded quite differently by the layman. The one spells ruin for the G.P.; the other is a natural event in a hospital fully staffed.—I am, etc.,

Maltby. A. H. BARTLEY.

Trichlorethylene as General Anaesthetic

SIR,—In view of the increasing use of trichlorethylene as a general anaesthetic we feel that the following case will not only be of interest but may perhaps serve as a warning too.

The patient, a woman of 25 with a nodular goitre showing no toxic symptoms, was chosen as a suitable case for trilene anaesthesia. Her electrocardiogram showed no abnormality, the pulse rate was 72, B.P. 115/75, and her Goetsch test for sensitivity to adrenaline was negative. She had the routine premedication for a thyroidectomy, which consisted of 30 grains of chloral by the mouth the night before operation, a further 30 grains of chloral 4 hours before operation, and omnopon 1/4 grain with scopolamine 1/125 grain hypodermically 1½ hours before operation.

She came down to the theatre quite calm and drowsy. After local infiltration of the thyroid area with 120 c.cm. of 0.5% procaine and 1:150,000 adrenaline, general anaesthesia was induced by 100% oxygen passed first over and then through trilene in a Boyle's bottle. Blind nasal intubation was performed after a few moments, and the patient's condition seemed to be satisfactory; she was breathing quietly and regularly and was a good colour. Her blood pressure taken immediately after intubation, however, showed that her heart was fibrillating at a rate of about 140 beats per minute. The systolic pressure was 140, the diastolic varied from 80 to 110. Her colour remained good. The trilene was discontinued immediately, 100% oxygen only being administered and the pulse continuously observed. After about 5 minutes the fibrillation was replaced by a series of coupled beats, quite forcible in character, the rate slowly decreasing. This continued for 40 minutes. Anaesthesia was continued under nitrous oxide and oxygen, using a high percentage of oxygen. When the operation was completed the pulse had become quite regular at 80 beats per minute and the B.P. was 140/90. She was returned to the ward in good condition and has made an uneventful recovery. An electrocardiogram taken 5 days later shows no organic change except some loss of ventricular tone.

The most probable cause of this patient's fibrillation seems to us to be the trilene. We have never seen a case of fibrillation during an operation in a case of non-toxic goitre with a negative Goetsch test, and we do not think the adrenaline is a likely cause in this case. The close resemblance chemically between chloroform and trichlorethylene should, on theoretical grounds at least, make us be on the look-out for abnormal cardiac rhythms. Dr. Langton Hewer,[1] in his recent review, suggests that there is no evidence of this drug having any marked toxic action on the heart, and an examination of the literature supports this view. Nevertheless we feel it is of value to record this case.—We are, etc.,

K. G. LLOYD-WILLIAMS.
Royal Free Hospital, W.C.1. DAVID HEWSPEAR.

Treatment of Scabies

SIR,—My attention has been drawn to the leading article on scabies (July 11, p. 44) in which some misconception as to the value of treatment by benzyl benzoate has crept in.

You state that benzyl benzoate is liable to cause an intractable scrotal dermatitis. It would be interesting to know what evidence there is for this statement. So far I have not seen it recorded, and from my own personal experience in a considerable number of cases I have not come across it. It has, of course, been recorded by several observers in the case of derris and rotenone preparations. There is some truth in the statement that the spirit soap preparation of benzyl benzoate gives rise to smarting when applied to the skin, especially when there is much secondary infection. This difficulty has, however, been overcome without loss of efficiency by the introduction of a benzyl benzoate emulsion. This emulsion has the further advantage of obviating the use of spirit and soap, both of which are at the moment in short supply.

While there is no doubt that the efficacy of the classical method of treating scabies by sulphur ointment has been amply proved, it has the disadvantage of being messy and, unless properly controlled, is liable to give rise to dermatitis. At the present time, when supplies of soft paraffin for the ointment and soap to wash the clothes are limited, this method is not, for economic reasons, well suited for treatment on a large scale.

The Advisory Committee on Scabies of the Ministry of Health, in the light of work done by K. Mellanby and others, has come to the conclusion that the preparation of choice is a 25% emulsion of benzyl benzoate prepared in accordance with the instructions in the *National War Formulary.* It is necessary to add that this treatment cannot be carried out satisfactorily by the patient himself, but must be applied by someone who has been given full instructions as to the application. This recommendation was accepted by the Ministry of Health and is repeated in the Ministry's revised *Memorandum on Scabies* which will appear shortly.

I may add that the Executive Committee of the British Association of Dermatology, after consultation with representatives of the Society of Medical Officers of Health, has come to a similar conclusion.—I am, etc.,

A. M. H. GRAY,
London, W.1. Chairman, Advisory Committee on Scabies

SIR,—I notice the opinion is expressed in your leading article of July 11 (p. 44) that sulphur ointment, properly applied, is the most effective and the easiest treatment available. This has always been the treatment advocated here, and it has met with considerable success. I agree with you when you say that the whole solution of the problem appears to be in the direction of more accurate diagnosis and not only inspection but treatment of contacts. I would like to add that it is desirable to master one method in detail rather than experiment with the most recently advertised remedy. You evidently consider benzyl benzoate a second best to sulphur, although a memorandum of the Ministry of Health dated April 30, 1942, describes a 25% emulsion as the preparation of choice.

---

[1] Hewer, Langton, *Proc. roy. Soc. Med.*, June, 1942, p. 466.

Two quite unnecessary instructions are commonly given to patients, doubtless copied from one book to another and from one set of directions to another. The first is to put on clean underclothes after the initial bath, and the second is to take a daily bath while under treatment. Since the essence of the sulphur method consists in thorough saturation with sulphur ointment for three or four days, and since baths of themselves do not cure scabies, there is no advantage, but rather the contrary, in taking them between the initial hot bath and the final hot one preceding terminal disinfection. Seeing that sulphur ointment treatment is admittedly somewhat messy, and bearing in mind that fomites do not carry infection to any extent and that in any case the underclothes will become saturated with sulphur ointment, there is no point in putting on clean underclothes after the initial bath as is commonly directed. Our routine directions run as follows:

Scabies is a contagious disease spreading readily from one person to another by contact and to a less extent by infected clothing and bedding. It is due to the itch mite burrowing in the skin and breeding there. The mite is very small and barely visible to a person with good eyesight. Cure is simple and certain if the following instructions are strictly followed, but it is most important to treat all affected members of a household at the same time and equally thoroughly, otherwise infection will persist and symptoms will return. The chief symptoms are itching spots on the hands, wrists, arms, legs, and elsewhere. The itching is worse at night or when the patient is warm.

Read Carefully

1st day.—Scrub yourself thoroughly in a hot bath with soap (preferably soft soap) and a nail brush. Cut finger- and toe-nails short. Dry yourself and while still warm apply the sulphur ointment well everywhere except face and scalp. Pay particular attention to skin between fingers and toes. Continue to use the same day and night clothes and bedding. The towel used must be boiled or placed in weak disinfectant and laundered.

2nd day }
3rd day } Once each day apply thoroughly fresh ointment over the old, rubbing well in. Do not bathe or change
4th day } clothing.

5th day.—Take a hot bath, preferably with a small handful of soda crystals in it. Wash off all the ointment. Put on clean clothes. All clothes and bedding used during treatment must now be disinfected.

Do not expect all itching to stop at once. Do not repeat treatment without medical advice. If itching spots return seek medical advice. It is most important to watch all members of the household for itching spots, and to make certain that all infected persons in the house are properly treated. Treatment, advice, and disinfection by the public health department are free.

—I am, etc.,

G. F. B. PAGE.

Exeter.

SIR,—I should like to be permitted to criticize under the following heads your leading article on the subject of scabies:

1. "Reproduction probably takes place both sexually and parthenogenetically." At the risk of displaying abysmal ignorance, I should like to ask for chapter and verse for this statement, as I have not previously encountered it.

2. "It appears that no substance has yet been tried which is superior to the old stand-by—the 10% sulphur ointment of the *B.P.*—or to the polysulphide preparation known as 'Marcussen's ointment' or 'kathiolan.'" This was certainly not my deduction from the paper of Mellanby, Johnson, and Barclay.

3. "The only other sarcopticide which gives results in any way comparable is benzyl benzoate, of which a 20% emulsion in soft soap and spirit appears to be quite satisfactory. There is, however, a serious objection to this application in that it is liable to cause an intractable scrotal dermatitis. . . . Moreover, it is not very suitable . . . for it always causes a certain amount of stinging, and if applied to a raw area . . . is extremely painful." It is evident that the pain and stinging are chiefly caused by the spirit, and the dermatitis by wartime soft soap. Both of these objections are very largely overcome by using aqueous emulsion of benzyl benzoate. The writer of your article has chosen for special mention the type of benzyl benzoate preparation which could give rise to objection, and has omitted the types which are nearly painless, and safe as well as effective. Personally, I find that aqueous benzyl benzoate emulsion is effective, safe, clean, easy to apply, and acceptable to patients, and am glad to find that it is held in good repute by those who should know.

4. I find myself in agreement with your remarks about the standard of diagnosis, and have to record that it took me many months to learn what I was looking for.

5. I regret that you have omitted to make reference to a standard of cure which is generally applicable to clinical as opposed to research practice. Personally, as the result of observation, I consider any sign of the disease within three months of treatment as a relapse, and am not prepared to accept a cure under that period. To me, therefore, series of cases which show a follow-up of only a few days are valueless, and indeed dangerous in that they tend to perpetuate a false idea of the value of various medicaments.—I am, etc.,

I. C. MONRO,
Medical Officer of Health.

Elgin.

⁂ The writer of the article on scabies got the impression that the acarus reproduced parthenogenetically from an article by Prof. P. A. Buxton in which it was stated that the pairing of *S. scabiei* has not been observed. On rereading the article (*B.M.J.*, Sept. 20, 1941) he admits he was wrong in drawing the inference of parthenogenesis from this statement.—ED., *B.M.J.*

Treatment of Malaria in England

SIR,—I have read with considerable interest the article on the diagnosis and treatment of malaria in England by Prof. Warrington Yorke (July 18, p. 61). There are one or two points in the suggested treatment which need comment. First, Prof. Yorke suggests the sulphate of quinine for the "ordinary" case. I am inclined to prefer the bihydrochloride, as it is more easily absorbed and is less of a gastric irritant. Furthermore, it can be combined with acid. hydrobromic. dil. to lessen the effects of "quinism," and with liq. arsenic. hydrochlor., a useful adjunct in malaria. Quinine should be prescribed with special reference to the cycle of the parasites and not in the stereotyped "t.d.s." manner. The ordinary "benign" attack usually starts at about 2 o'clock every third afternoon, which means that the parasites begin to invade the blood stream at about this time. It was therefore my custom to get into the circulation as much quinine as possible before the parasites began their "invasion." I accordingly gave the required doses at 6 a.m., 10 a.m., and 2 p.m.

In his treatment of the more severe types of malaria, Prof. Yorke suggests intravenous quinine in 1/2 to 1 pint of 3% saline. Intravenous quinine is admittedly the only remedy, but 20 c.cm. of distilled water or saline is all that is necessary, particularly in general practice. It is considered advisable to add a minim or two of 1 in 1,000 adrenaline chloride solution when giving intravenous quinine. Organic arsenic intravenously seems to help in chronic or resistant cases. An occasional injection is all that is necessary.—I am, etc.,

London, W.1. E. S. FENNELL.

Recommendations of Radium Commission

SIR,—The recommendations of the Radium Commissioners outlined in your issue of July 11 (p. 48) call for certain comments. The first concerns the status of the Commissioners themselves. On this point the Cancer Act is quite clear. The initiative in implementing the Act rests solely with the county councils, who, after consultation with the staffs of the local hospitals and with local organizations of registered medical practitioners, shall submit their arrangements for the approval of the Minister. The Radium Commissioners are not mentioned from beginning to end.

On Feb. 13, 1939, during the third reading of the Cancer Bill, on the proposal of the Minister of Health, Dr. Walter Elliot, a provision whereby local authorities must consult the Radium Commissioners was deleted and replaced by another provision whereby the Minister was to be advised by a subcommittee of the Medical Advisory Committee. It was understood that local authorities might, if they wished, consult the Radium Commissioners, but only informally. Dr. Elliot expressed the hope that this plan would meet the fear of some Members that radium was given too prominent a place in the Bill, and that local authorities were going to be placed under a technical commission. The fears of these Members were well founded. Dr. Elliot no doubt meant what he said, but he was evidently not binding his successors; for the Commissioners, so far from being relegated to the background as was the intention of Parliament, continue to dominate the situation, urging the country to get on with the job and telling us how to do it.

Among other things, they recommend that each centre should be under a whole-time director and that the radiotherapist (who may or may not be the director) should be in full charge of all radium and *x*-ray therapy. This means that those of us who use *x* rays only would be faced with the alternative either of subordinating ourselves to men less experienced in *x*-ray therapy than ourselves or of going out of business altogether, losing our practices and our main interest in life. No doubt the Commissioners regard me and those like me as obstacles to the cure of cancer, so much dead wood to be removed before everything in the garden is made lovely.

Some of us began *x*-ray therapy long before the Commissioners were thought of. For many years we have instructed and examined for the diplomas most of the younger radiologists in the country. For many years the patients from one of the Commission's own radium centres in another town have been sent to me because the Commissioners failed to provide *x*-ray therapy, being apparently unaware of its necessity. Most radium centres, having failed to obtain the results they expected from radium, have come to rely more and more on *x* rays, and some of them have sought my advice regarding technique. Even after the fiasco of the Erlangen school in the early 'twenties a few of us retained our faith in *x*-ray therapy. It was we who, through years of scepticism, discouragement, and sometimes scorn, rescued and nursed it, believing that the craze for radium, then in full swing, was not destined to last. Events have proved that we were right; for, except in a few situations, radium treatment must, in relation to the magnitude of its promise, be accounted one of the major disappointments of medicine. We backed the right horse, the Radium Commissioners backed the wrong one. They backed our horse when the race was over and now they calmly propose to relieve us of our winnings.

It is, of course, essential to ensure that radium is, within its limited sphere of action, only administered on scientific principles, but this end can be achieved without penalizing those of us who bore the burden and heat of the day in proving to the Commissioners and others the superior merits and wider applicability of *x* rays. Whether it is in the public interest that those of us who showed a sounder instinct than the Radium Commissioners should now be prevented by them from continuing our work I leave it to your readers to judge. In my opinion, where there is so much to learn, every shade of thought and line of inquiry should be allowed to develop unfettered by artificial restrictions.—I am, etc.,

Cambridge FF. ROBERTS.

District Nursing Service

SIR,—Lord Horder, writing as Chairman of Council, Greater London Provident Scheme for District Nursing (July 25, p. 109), must surely be referring to London only when he says that "much too little use is made by doctors with panel practices of the facilities afforded by the district nursing service."

B.M.A. figures for 1937 show that out of 26,520 general practitioners 17,787 were engaged in panel or "mixed" practices. Figures for 1938 show that out of a population of 46,200,200 there were 19,959,000 entitled to National Health Insurance benefit. It is generally accepted that the latter, with their dependants, account for over 90% of the population. This being so, it would appear that the bulk, if not the whole, of the district nursing services is concerned with panel patients and their dependants, and if the district nurse is a busy person it may well be because her services are made use of by the panel doctor. Where her services are not fully used by a particular panel doctor it has to be remembered that there are degrees of competence in nurses as well as in doctors; sometimes, perhaps, she is not always to be relied upon and the doctor is wise to insist upon seeing the patient himself. Lord Horder instances a case of cellulitis, but we do not know what this means. Perhaps the patient was very ill and should have been in bed; or perhaps it was a mild cellulitis of the finger and the doctor wished to trust to no judgment but his own as to the course that the infection was taking; or perhaps it was discharging pus and perhaps the nurse was in attendance upon one of this same doctor's midwifery cases.

I venture to suggest that Lord Horder's reproof, while no doubt justified in certain instances, is altogether too general, and that the panel practitioner above all others has the most reason to hold in high regard the services provided by district nurses, without whose help he could hardly sustain his work.—I am, etc.,

Buntingford, Herts ALAN WIGFIELD.

Urethral Instrumentation

SIR,—I should like to endorse Dr. Vincent Norman's restrained and convincing reply (July 18, p. 80) to Mr. Gordon Bohn's letter on urethral instrumentation.

Mr. Bohn's letter (July 4, p. 25) is an example of the tendency among some specialists to treat the G.P. with contemptuous tolerance, and though the tendency is confined for the most part to the lesser lights and to the less experienced among the specialists, this attitude of mind appears to wax and wane from time to time. To-day it appears to be increasing, and that it should be so is all the more unfortunate when so much is being written and discussed concerning the medical service of the future.

In an article entitled "The G.P. as the Basis of the Medical Service of the Future," which appears in the *Supplement* of July 18, the following observation occurs: "That the G.P. service should be given such a position that it will not fail to attract men of a calibre reasonably equal to that of the specialist." But what is this calibre? Surely the calibre of the specialist is as variable in worth as is the calibre of the G.P. The far-sighted, expert, and experienced specialist understands and appreciates the worth of the G.P. as fully as the fighter pilot appreciates the worth of his ground staff, but to those who cannot attain such a state of mind, may I suggest that they should assimilate the following facts: (1) that the specialist is much more often the product of his unusual opportunity than of his unusual intelligence and skill; (2) that though the specialist may inveigh against the occasional errors of the G.P., the G.P. has to take the largest share in, and to continue to treat, the consequences of the no less frequent errors of the specialist; (3) that the G.P. has to be competent and knowledgeable about many things to earn a living, but that the specialist has usually to be competent in a much smaller and more highly paid field.

It is, I believe, this last paragraph which explains the attitude of some of the specialists towards the G.P. The specialist, because his scope is small and his earnings large, in some cases tends to become insular and arrogant in his views, and, as Dr. Norman observes, "offers evidence of the fatuous and narrow outlook of the one-specialty man."—I am, etc.,

Hampstead, N.W. H. J. S. MORTON.

SIR,—The teaching of urethral instrumentation advocated by Mr. Clifford Morson (June 20, p. 771) is in my opinion most important, and in elderly persons the relief obtained by the catheter for retention of urine due to obstruction caused by prostatic enlargement is immediate and safe. The acute discomfort and pain of a distended bladder is immediately relieved, and it is only by the passing of the catheter that the nature of the cause can be clearly discovered, as no local or rectal examination can make the cause obvious, but a suprapubic palpation will always be necessary and should not be overlooked. I am not referring to organic nervous disease or atony of the bladder, but to retention due to enlarged prostate. I have seen the rubber catheter (normally No. 8 or No. 9) used for years without any unfavourable symptom, and I can speak from personal experience and from the history of other sufferers from prostatic enlargement. I have never seen any haemorrhage from the kidney or bladder, but I have known of ruptures of the bladder walls from over-distension, when the outflow of urine is hampered by obstruction and when a catheter would afford relief.

I do not refer to spasm of the sphincter or to obstruction associated with prostrating diseases of the nervous system. During catheterization the contraction of the detrusor muscle keeps the bladder wall continuously in contact with the urine until it is completely voided. There is consequently no negative pressure (through the gradual emptying by the catheter) which can favour haemorrhage. The relief to the sufferer is immediate and is most gratifying.—I am, etc.,

London, W.8. F.R.C.S.

Epididymitis after Acute Gonorrhoea

SIR,—Lieut.-Col. T. E. Osmond's letter (April 18, p. 507) calls for a reply.

The patient had a right epididymitis. In my opinion this is invariably caused by spread along the right vas from the right seminal vesicle. In the tests of cure and investigation no mention is made of having obtained any sample of secretion from the seminal vesicles, though prostatic beads were free from pus. How much prostatic and vesicular massage was given is not stated, but if adequate drainage was not obtained from the right seminal vesicle relapse was to be expected.

The difficulty in obtaining a specimen from the seminal vesicle is considerable, and the fact that four different venereologists, all experienced medical officers, did not obtain it does not mean that this was not the focus of infection.—I am, etc.,

Capetown. F. W. F. PURCELL.

Active Rehabilitation by C.S.M.M.G. Masseuses

SIR,—Mr. G. O. Tippett has drawn attention in his letter to the truly magnificent work of the R.A.F. orthopaedic centres. The treatment of injuries by active methods—i.e., the maintenance of function during fixation, rather than the restoration of function after fixation—is a basic orthopaedic principle. The organized practice of this principle has been of slow but steady growth. It has, however, received impetus during the war because the expansion of hospital services has given greater opportunity to segregate cases of injury of certain types, and to create a new and better organization to deal with them. It is greatly to the credit of the orthopaedic representatives at the several Ministries that they have taken advantage of these opportunities.

Although Mr. Tippett noticed that the medical officers at the R.A.F. centre he visited were personally teaching and helping their patients, he seems to have failed to appreciate fully the significance of this. Rather, seeking to cast out the mote from his brother's eye before considering the beam in his own, he has tried to lay on members of the C.S.M.M.G. the blame for deficiencies at the hospitals with which he is associated. If he really imagines that chartered masseuses can only give massage and faradism to an injured limb, he is sadly out of date. Members of the Chartered Society are required by its ethical code to work only to the instructions of a qualified doctor. If that doctor (or surgeon) fails to prescribe modern methods of treatment he has only himself to blame; and if he has not the facilities he must blame the organization for which he works, not the C.S.M.M.G. The syllabus of the Chartered Society has been modified to lay emphasis on modern methods of rehabilitation, and post-graduate courses organized by the society are in progress.

There is a first-rate organization for the rehabilitation of the injured at many hospitals of the War Office, the B.R.C.S., the Ministry of Health, and the Ministry of Pensions, as well as the R.A.F. It is true that many other hospitals are backward in this respect, but it is up to us, as orthopaedic surgeons, to overhaul our methods and reorganize our departments. I find chartered masseuses are the keenest and most co-operative people with whom I am associated. I can assure Mr. Tippett that if he will make the effort necessary to introduce modern methods where he works, his masseuses will not let him down.—I am, etc.,

PHILIP WILES, M.S., F.R.C.S.,
London, W.1. Vice-Chairman of Council, C.S.M.M.G.

SIR,—It is astonishing to read in Mr. G. O. Tippett's letter (July 18, p. 81) that "the best effort a masseuse of the C.S.M.M.G. can do is her routine stock-in-trade of massage and faradism to the injured limb." The Chartered Society examines candidates trained in the latest methods of rehabilitation, and the masseuses are fully alive to the scope of modern rehabilitation, which includes heat, massage, galvanism, faradism, diathermy, short wave, ultra-violet light, hydrotherapy, and rehabilitation exercise plus occupational therapy and games.

I feel sure that Mr. Tippett would be surprised if he made excursions from his narrow sphere where patients "lie in plaster and physically rot in bed or loaf about on a stick." I would suggest that he visits the Sector Hospitals and London and provincial teaching hospitals, where he would find departments and wards equipped with suspension sling apparatus, either the standard metal unit or the makeshift Balkan beam unit and modifications; he would find the patients treated from the earliest possible moment in recumbency by progressive active weightless exercise, graded up to active resistance exercise and games, with certain hours allocated to occupational therapy, orthopaedic and diversional in type.

I feel that Mr. Tippett and others must be unaware of the progress in rehabilitation exercise which has been taking place since this war broke out, and also the good results obtained not only in fracture cases, but in spondylitis, peripheral neuritis, poliomyelitis, and rheumatoid arthritis cases, apart from multiple injuries sustained in air raids. The C.S.M.M.G. masseuse has a high ideal and a good training in modern methods, and cannot be blamed if the hospital is unable to afford the necessary ropes, slings, springs, etc., required for modern rehabilitation; no doubt some civilian hospitals may be restricted through lack of funds and the masseuse's efforts appear feeble. It is up to the physicians and surgeons to make full use of the trained C.S.M.M.G. masseuse and "go to it"; the C.S.M.M.G. masseuse and Chartered Society have gone to it!—I am, etc.,

London. N. I. LANCKENAU.

Body Mechanics

SIR,—The theories advanced by the authors of *Body Mechanics in Health and Disease*, which was reviewed in your issue of July 25 (p. 99), are similar to those propounded by Andrew Taylor Still, the original osteopath, 80 years ago, and which have had attention drawn to them since by many others, including myself. Still's conceptions have been disregarded or strenuously denied by the medical profession: now that they are put forward, however, by those with accepted medical qualifications who have been careful not to use the word "osteopathy," these theories are apparently to be given kindly encouragement by the medical profession.

On account of the unfortunate antagonism between the medical and the osteopathic professions—and there are faults on both sides, no doubt—valuable time, experience, and personnel have been, and are continuing to be, wasted. Is it not possible, even at this late stage, for this misunderstanding to be resolved?—I am, etc.,

London, W.1 GEORGE MACDONALD.

Diarrhoea and Vomiting

SIR,—Your annotation under the above heading (July 25, p. 102) prompts me to send you some views I have been forming on the subject in the course of investigations made into the nature of epidemics.

Diarrhoea and vomiting, in an epidemic form, may be more common in infants than older people, but they are of frequent occurrence in the latter and of particular importance as heralding what is to occur in the following winter. Diarrhoea and vomiting are the most common initial signs and symptoms of infections from within, caused by the developmental forms of the *B. coli communis*, resident in the intestinal tract. Although any one of these forms may be the causative micro-organism, the most active are those belonging to the *Proteus*, *Salmonella*, and dysentery groups; and these and the other micro-organisms ring greater changes in infants than in older people, because the former have had less time to develop an immunity against them.

These signs and symptoms are the initial ones of infections from within, because, owing to the micro-organisms residing in the large intestine, the portal system is the one to be first involved on their becoming active; and thus an explanation is afforded for their incidence in the summer months being a prelude of what is to happen in the winter months. Diarrhoea and vomiting are most common between June and October, because heat augments the other climatic factors which govern infections from within to account for their developing cyclically. An annual cycle is to be detected where the nadir and zenith of the host's resistance are found to occur most commonly in the months of July and January. The chemico-physical changes which the protein in the plasma (wherein resides the host's resistance) undergoes at the hands of climate are the second factor governing infections from within. The micro-organisms in the colon come third, because their activity is determined by the state in which the host's resistance happens to be. Diarrhoea and vomiting have been more common this summer than for some years past; consequently I venture to predict that we will not be so free from influenza next winter as we have been in the last few winters.—I am, etc.,

London, W.1. J. E. R. McDONAGH.

A Depression–Hyposexual–Alopecia Syndrome

SIR,—This interesting case (July 18, p. 67) has unfortunately not been fully investigated. No mention is made of the physical condition apart from the loss of hair, nor of any investigations regarding metabolism (B.M.R., blood sugar, blood cholesterol, blood morphology, etc.), the condition of the pituitary fossa, and other items indispensable for an endocrine diagnosis. Not even the blood pressure or the result of a urinary routine examination has been recorded.

The syndrome itself is not unknown to the endocrinologist. It can occur either as the result of a pituitary (or pituitary-diencephalic) disturbance, representing a beginning or mild form of Simmonds's disease, or it can be of thyroid origin and represent a beginning or masked myxoedema. In both conditions complete loss of hair has been observed, loss of sexual function and mental depression being well-known symptoms of either of them. The onset after vaccination is slightly more suggestive of a lesion affecting the pituitary or the base of the brain, but hypothyroid conditions can occur after any infectious disease.

A proper examination of the patient would probably throw enough light on the nature of his condition to avoid its being regarded as a new endocrine syndrome.—I am, etc.,

London, W.1. H. UCKO.

Saving Cotton-wool and Using Sawdust

SIR,—I was much interested in the article on the use of sawdust as a dressing by Mr. Fitzwilliams because I have used this dressing. I was particularly impressed with its value in a case of psoas abscess with which I had to deal many years ago. A profuse discharge of pus was absorbed by and diffused through the sawdust, and the surrounding skin was kept dry.

A full account of the method of its use will be found in *A Surgical Handbook* by Caird and Cathcart, a book full of wise counsel and in much request during my student days in Edinburgh. I found, as Mr. Cathcart taught, that sawdust from pitch-pine was the most satisfactory.—I am, etc.,

Bushey, Herts. THOMAS FENTEM, M.D.

SIR,—In view of Mr. Fitzwilliams's statement (July 25, p. 105) that one of the reasons for using cotton-wool is its absorbent qualities for septic wounds or where there is discharge the following should prove of interest.

To investigate the properties of various dressings as aids to drainage the following experiment was performed. Lengths of gauze, home-made plaster, and "cellona," 1½ inches wide and eight layers thick, were marked at one-inch intervals. The ends were placed into a bowl containing either citrated blood or coloured water, and the transmission of the fluid noted at various time intervals. The actual figures are not quoted because they varied so much with each experiment, but constant comparative results were obtained. These were: (1) that the transmissibility of the gauze was the most rapid up to six to ten hours, when it was overtaken by the home-made plaster, and that "cellona" in the 24-hour period remained inferior to both; (2) that the transmissibility was more rapid at the start and gradually diminished with increase in the time period; (3) that the transmissibility increased when the materials were dependent. Various other substances were tried, such as jaconet, felt, and bandage, all of which showed no tendency to transmit. Brown wool merely floated on the surface of the fluid. White wool deserves special mention because it is so frequently stated to be a satisfactory dressing owing to its absorbent qualities, but the experiment showed that only the portion submerged in the fluid absorbed and became weighted, and that there was no transmission whatsoever above the fluid level. As a close dressing, therefore, it is useless, as only that part in actual contact with the discharge is absorbent. Since there is no direct transmission it will only serve to retain the discharge in proximity to the wound and macerate the skin. This has been repeatedly noted clinically. When wool is used it should be employed only as an external covering, and should be separated from the wound by a pad of gauze several layers thick.

Hence rather than an economic alternative to cotton-wool, sawdust is a better dressing as it absorbs and transmits well.—I am, etc.,

G. MARIANI,
Senior House-surgeon,
Radcliffe Infirmary, Oxford. Accident Service.

Obituary

F. DAWTREY DREWITT, D.M., F.R.C.P.

The death of Dr. Frederic Dawtrey Drewitt on July 29 takes from us a physician and naturalist of wide culture and most kindly disposition, a connoisseur of beautiful and interesting things, who was held in affection by friends, old and young, throughout a very long life. Born on February 29, 1848, he was educated at Winchester, at Christ Church, Oxford (where he won second-class honours in Natural Science), and at St. George's Hospital. He qualified M.R.C.S. in 1876 and took the M.R.C.P. in 1879. At Oxford he graduated M.A. and B.M. in 1878 and D.M. in 1883. He was elected F.R.C.P. in 1888. After house-physicianships at St. George's and at Great Ormond Street he held the post of physician to the Victoria Hospital for Children, Chelsea, from 1881 to 1897. At the West London Hospital he was assistant physician and later physician from 1882 to 1902, and then served for many years on its board of management. In an address in 1907 H. H. Clutton wrote: "Attention was first called in England to adolescent or late rickets by Dr. F. G. D. Drewitt, who showed a boy aged 10 years at the old Pathological Society of London in November, 1880. The boy was in the Great Ormond Street Hospital under the late Dr. W. B. Cheadle, and died two years later, when a post-mortem, made by Sir Thomas Barlow and Dr. P. Abercrombie, showed that the case was one of true rickets."

Dawtrey Drewitt was a lifelong student of Nature. He spent thousands of happy hours watching birds and naming wild flowers, or sketching in the open at home and abroad. He had served on the committee of the British Ornithologists' Union, and for many years on the Councils of the Zoological Society, the Society for Promotion of Nature Reserves, and the National Trust for Places of Interest or Beauty. Until 1941 he represented the Royal College of Physicians on the committee of management of the Chelsea Physic Garden, which he frequently visited as its vice-chairman, and his pleasant little book *The Romance of the Apothecaries' Garden in Chelsea* went into a third edition. He also wrote books on *Bombay in the Days of George IV*; and on the *Latin Names of Common Flowers: Their Pronunciation and History*, and a second edition of his *Life of Edward Jenner* appeared in 1933. His sensitive eye and delicate touch were revealed in many water-colour sketches and etchings, some of them shown publicly at the Royal Academy, and in more recent years at medical art exhibitions. At the age of 94 his handwriting was a miracle of shapeliness and legibility.

His well-stored mind, his lively interest in the world around him, and his charm of manner and appearance made Drewitt a welcome companion at the Savile Club (which he had joined in 1877), at the United University Club, at the dining club of the Royal College of Physicians, and at the periodical dinners of the Lucretian Club, which he attended until well past the age of 90. His sixtieth year of membership of the Savile was celebrated by a dinner party given in his honour in the club house. He bore the disabilities of old age with gentle good humour, and the bombardments of London could not shake his spirit. Though very frail and lonely towards the end he never complained or expected others to put themselves out for him.

MARK RONALD TAYLOR, M.R.C.S.

The death took place at Formby in Lancashire on July 22 of Dr. Mark Ronald Taylor, who was for many years before his retirement a regional medical officer of the Ministry of Health.

He was born in 1871 the son of Thomas Taylor, a surgeon of Bocking, in Essex, who had qualified in 1841, so that between them father and son completed a hundred years' continuous service in the medical profession. Mark Taylor received his education at Rossall and St. Bartholomew's. He qualified in 1894 and started practice at Helston, where for ten years he was also medical officer of health. In 1915 he moved to Acton and was surgeon to Acton Hospital. Both in Cornwall and in Middlesex he was a prominent member of the Insurance and Panel Committees and the Medical Service Subcommittee, and in 1920 he was appointed one of the first batch of whole-time regional medical officers of the Ministry of Health, being stationed for seven years at Norwich and afterwards at Southampton.

For the ten years 1904 to 1913 Dr. Taylor was honorary secretary of the West Cornwall Division of the B.M.A., and, for a while, of East Cornwall too, while that Division was being pulled together. During his term of office he initiated two reforms which eventually affected the whole county. One of these was the placing of the district nursing service on a proper basis. At that time many districts seemed to make their own rules, with the result that some nurses prescribed and dispensed, and some even attended fractures and serious eye troubles without reference to any doctor. In consultation with two other prominent members of the Association, Taylor drew up a set of rules which were adopted, and two medical men were co-opted on to the committee of the District Nursing Association. The other matter was his successful resistance to the suggestion that doctors should give courses of Red Cross lectures for nothing. Taylor was a valiant fighter, and in the West of England, where he was practising at the time and represented his Division, the fight over the National Health Insurance Bill was long and bitter.

In recent years, after his retirement, Taylor went to live near Liverpool, where he continued to do some part-time work for the Ministry, and, until his last illness, served on Medical Boards. He was a keen naturalist and an ardent angler, inventing a number of gadgets which increased the scientific interest in fish and fishing. He was also an earnest student of folklore, and wrote much on the subject. While in Norwich he collected material for a good-sized book on East Anglian folklore, medicine, and magic, but never published it.

GEORGE KEPPIE PATERSON, M.B., F.R.C.P.Ed.

Edinburgh has lost a venerable figure by the death of Dr. G. Keppie Paterson, who had been for more than half a century associated with the Livingstone Dispensary in the Cowgate, of which he was consulting obstetrician and physician for maternity welfare at the time of his death.

George Keppie Paterson was born in 1861, and took his M.B., C.M.Ed. with honours in 1882. Afterwards he studied in Berlin and Vienna. For ten years he was assistant to Sir Alexander Simpson, the holder of the chair of midwifery and diseases of women in Edinburgh University. He acquired an extensive general practice which he carried on until a few years ago. He became in 1891 a member of the Royal College of Physicians of Edinburgh and in 1895 a Fellow. He was one of the oldest members of the British Medical Association, his membership extending over 58 years. In 1903 he became hon. secretary of the old Edinburgh North-East Division, an appointment he held until 1911, and then, for a further ten years, he was hon. secretary of the new Edinburgh and Leith Division, of which in 1924-6 he was chairman. In 1930-1 he was president of the Edinburgh Branch.

One of Dr. Paterson's greatest interests was medical missions. He had travelled extensively in North Africa, Egypt, Palestine, and the West Indies. He joined the Edinburgh Medical Missionary Society in 1890, and was for several years its hon. treasurer and vice-president. It was an abiding joy to him that his professional services during almost the whole of his career should be given to an institution which bore the name of Scotland's greatest medical missionary. Dr. Paterson was a man of high culture and greatly respected in his city. One of his keenest interests was in music, and he even ran a choir in his dispensary.

PROFESSOR MARFAN

Prof. Antonin Bernard Jean Marfan, the eminent Paris paediatrician, whose death without mention of the date is reported by the *Schweizer Medizinische Wochenschrift* of May 9, was born at Castelnaudary in the Aude Department of France on June 23, 1858. He received his medical education at Toulouse and Paris, where he qualified in 1887, and five years later obtained the coveted post of Médecin des Hôpitaux. In 1914, when he was elected a member of the Académie de Médecine, he became the first occupant of a chair of infantile hygiene, and held this post until his retirement in 1928. For many years he was physician to the well-known Hôpital des Enfants Malades in the Rue de Sèvres with special charge of the diphtheria block. His literary output was considerable and of a high order. His principal work was a treatise on lactation which went through four editions and may be regarded as a classic. He was also the author of a monograph on diphtheria, a series of volumes on diseases of infants, and shorter works on periodic vomiting with acetonaemia, puncture of the pericardium by the epigastric route, and diagnosis of sore throat. Besides being founder and editor of the quarterly journal *Le Nourrisson* he was co-editor of the *System of Medicine* with Charcot, Bouchard, and Brissaud, and of the *Treatise of Children's Diseases* with J. Comby. He was well known in this country, where he was elected an Honorary Fellow of the Royal Society of Medicine in 1934.

Universities and Colleges

UNIVERSITY OF CAMBRIDGE

The following candidates have been approved at the examination indicated:

DIPLOMA IN MEDICAL RADIOLOGY AND ELECTROLOGY—*Part II*. G. K. F. Cohen, R. McK. Crichton, T. Culloty, F. Freund, Maria E. Grossman, H. T. Halper, H. R. C. Hay, C. J. C. G. Hodson, D. A. Jennings, M. B. Leitch, J. McM. Mennell, D. J. Mitchell, R. G. Moffat, J. Y. Rabinowitch, Katharina Rosenkranz, A. W. Simmins, J. H. Smitham, Lilian H. Walter.

At a Congregation held on June 20 the following medical degrees were conferred:

M.D.—*G. L. Robinson, *G. O. Richardson, *E. F. Aubert, H. J. V. Morton, R. W. Mason, D. J. Watterson, E. J. C. Topham.

* By proxy

UNIVERSITY OF LONDON

F. G. Young, D.Sc., Ph.D., has been appointed to the University Chair of Biochemistry tenable at St. Thomas's Hospital Medical School. B. W. Windeyer, M.B., B.S.Syd., F.R.C.S.Ed., F.F.R., has been appointed to the University Chair of Radiology tenable at Middlesex Hospital Medical School. Alexander Lawson, Ph.D., B.Sc., has been appointed to the University Readership in Organic Chemistry tenable at the London (R.F.H.) School of Medicine for Women.

WESTMINSTER HOSPITAL MEDICAL SCHOOL

An examination for two entrance scholarships in anatomy and physiology will be held on Sept. 9 and 10. Particulars may be had from the Secretary, Westminster Hospital Medical School, 17, Horseferry Road, S.W.1.

ROYAL COLLEGE OF OBSTETRICIANS AND GYNAECOLOGISTS

At a quarterly meeting of the Council held in the College House on July 25, with the President, Sir William Fletcher Shaw, in the chair, the following officers were elected to take office in October:

President: Sir William Fletcher Shaw. *Vice-Presidents:* Mr. William Gough and Mr. C. G. Lowry. *Honorary Treasurer:* Mr. J. P. Hedley. *Honorary Secretary:* Mr. G. F. Gibberd. *Honorary Librarian:* Wing-Cmdr. F. W. Roques, R.A.F.V.R. *Honorary Curator of Museum:* Mr. Aleck W. Bourne.

L. C. L. Averill (New Zealand) was admitted *in absentia* to the Fellowship of the College.

The following candidates were elected to the Membership:

H. Agar, Muriel Boycott, J. W. D. Buttery, Marie H. Calverley, T. A. Gillie, I. MacG. Jackson, W. J. McCord, Mary K. Lawlor, H. M. Wolff, J. F. B. Wyper.

Medical Notes in Parliament

Health of the Factory Worker

Mr. **ERNEST BEVIN**, on July 22, presented the estimates for the Ministry of Labour. He recalled the transfer of the Factory Department and its administration from the Home Office to the Ministry of Labour and National Service in June, 1940. Factory inspection and welfare could not be separated from the mobilization and use of man-power. The transfer placed long and valuable experience at the disposal of the Ministry when dealing with the problems of the movement of workers and the physical strain of war conditions. He was happy to say that notwithstanding the bombing of homes and of factories, the health of the population had stood up to the strain. He regretted that the accident rate in factories had increased owing to recruitment of inexperienced workers and expansion of dangerous industries. The Ministry had given attention to problems of skin disease arising out of the war, and, all things considered, the percentage rate was low. Removal to other occupations of workers who were prone to such disease and sick-bays in hostels for immediate treatment had helped to keep it under control.

During the last two years medical supervision and nursing services in the factory had been intensified, and as a result absenteeism had been reduced. Co-ordination between the works doctor and the general practitioner shortened illnesses. Works doctors were valuable in organizing first-aid arrangements and keeping them efficient. They could look after workers who were exposed to special risks, and they performed a great educational service. They attended to the special problems affecting juveniles. The number of doctors employed whole-time increased during the last 2 years from 35 to 150, and part-time doctors from 70 to 550. The Ministry set to work to organize this part-time service for the smaller factories, but was handicapped by the call-up of doctors for the Services. He hoped this work would not be allowed to die at the end of the war. It was additional to the statutory work of the examining factory surgeons and to less comprehensive services in many other factories. He was studying how the certifying surgeons and the examining factory surgeons could be brought more fully into the picture as integral parts of the industrial health services. The technique developed in industrial medicine could be of tremendous value to the medical services of the country as a whole. The Ministry had sought to expand the factory nursing service rapidly and had provided short courses of instruction in conjunction with the Royal College of Nursing. The training continued after the nurses had gone to the works, with the aid of the medical people employed. Hours of work in factories were a vexed problem. After Dunkirk there appeared a danger that the Factory Acts administration would break down. But now man-power had been so mobilized that he was considering the tightening up of hours at an early date.

Tuberculosis Related to Black-out Conditions

Mr. **ELLIS SMITH** cited a report of the British Medical Association on the health of industrial workers. He said that in too many cases the milk supply to workers engaged in dangerous processes had been stopped. He hoped the lessons of the investigation into silicosis among anthracite workers would be applied to the pottery and asbestos industries. He asked for a national scheme of rehabilitation to be established as soon as possible. Mr. **MCNEIL** said Mr. Bevin had power to place a medical man within any factory as a servant of the Crown if he did so within the terms of the inspectorate. Figures published that week showed that in Glasgow the rise in tuberculosis was almost confined to the industrial workers. For commercial and professional workers who had not to undertake night-shifts in black-out conditions the figures were almost stable. Mr. **LEWIS JONES** complained that the report of the Chief Inspector of Factories did not relate the accidents to the number of people employed.

Doctors' "Notes"

Mr. **SIMMONDS** remarked that whereas there was normally in the winter and spring maximum absenteeism due to bad health, in a number of factories this year absenteeism had been continuing into the summer. In some, absenteeism in June was worse than in any of the spring months. Either the workers were suffering from industrial fatigue resulting from the winter or else there was, now the weather was better, more pressure on the doctors to certify that workers were in need of a rest. Many doctors were now shockingly overworked, and some were not as careful as they ought to be in issuing certificates for absence. Tightening up was essential if production was to be maintained.

Dr. **HADEN GUEST** said Mr. Simmonds should supply details of his allegations to the Ministry of Labour. Dr. Guest believed they could not be substantiated. He hoped that medical supervision in factories would be increased and extended, and that still more stress would be laid on the preventive side of the doctor's work. Works doctors should consult weekly with representatives of the employees on matters affecting well-being and health. He wondered whether the committee under Sir Geoffrey Shakespeare could give a special medical quota for works.

Sir **GEOFFREY** intervened to say the problem had been considered by the Priority Committee and efforts were being made to meet the demands of the Ministry of Labour.

Dr. **GUEST** said the position could also be improved by employment of women doctors. It should be possible to get some of the retired or semi-retired older medical men and women back for this kind of work. Was it possible for panel doctors who were in attendance on the workers in a district to attend to the preventive side of medicine in the factories? Mr. **HIGGS** produced specimens of doctors' "notes." One, which stated "is unable to follow her employment owing to her aunt's illness," had been accepted by the timekeeper. These doctors' "notes" were issued far too liberally.

Mr. **TOMLINSON**, replying to the debate, said the British Medical Association and the Trades Union Congress both felt that industrial health work was on the right lines. Asked about discoloration of workers in contact with certain powders, he said the scientific resources of the Allies had been brought in to find a solution. They might find something which would turn girl workers a healthy tan instead of a dirty yellow. The Ministry had failed to determine what were the detrimental effects of black-out on the worker, but believed they were more psychological than physical.

Parliamentary Health and Housing Committee

Lieut.-Gen. Alexander Hood, Director-General of Army Medical Services, on July 21 attended a meeting of the Parliamentary Conservative Health and Housing Committee under the chairmanship of Sir Francis Fremantle. General Hood gave an encouraging account of health conditions in the Armies both at home and abroad, but said increased vigilance would be necessary during the coming winter when hutments and billets would have to accommodate increasing numbers. With advisory bodies to keep it in touch with civilian practice, his Department was now organized on a basis that ensured a complete medical service for the troops.

Mr. Hugh Linstead was elected deputy secretary of the committee to assist Capt. G. S. Elliston, who has been hon. secretary of the committee since 1931.

Compulsory Vaccination and Inoculation

Asked on July 23 by Sir **WALDRON SMITHERS** to take the necessary powers to make vaccination against small-pox and injections against other infectious and epidemic diseases compulsory, Mr. **BROWN** declined to do so. He said that recent occurrences had not afforded any justification for such a change of policy, but he would continue to do all in his power to encourage immunization against certain infectious diseases, either as a routine or when special circumstances called for such action.

Appeal Tribunals

Sir **WALTER WOMERSLEY** announced on July 23 that at present it was not possible to set up tribunals to deal with all the appeals that would be made on war pensions. He was taking full advantage of the arrangement under which cases of serious doubt or difficulty on a medical question could be referred to an independent expert nominated by the President of one of the Royal Colleges. In no case had he rejected the opinion expressed by one of these experts. The medical referees were independent of his Department and were under no pressure from him. Appeal tribunals would be set up as soon as practicable without waiting for the end of the war if doctors should become available. Possibly medical personnel might be spared from the Army.

Deaths from Pernicious Anaemia

Mr **BROWN** stated in the House of Commons that the number of deaths from pernicious anaemia registered in England and Wales in 1939 was 1,922; in 1940, 2,167; and in 1941, 2,422. The figures for 1939 were corrected to agree with the 1940 classification of deaths and differed from those published in the Registrar-General's *Statistical Review*, Part I, Table 6.

M.R.C.: Tuberculosis Report

The report of the Tuberculosis Committee of the Medical Research Council is almost complete. It will contain interim recommendations on the steps to be taken forthwith. They will deal with the increased incidence among children under 5 years of age and inmates of mental hospitals.

The Services

CASUALTIES IN THE MEDICAL SERVICES

Temp. Surg. Lieut. **Cameron Fraser**, R.N.V.R., who, in the *Journal* of May 30, was reported missing, is now posted as "Missing, Presumed Killed" in H.M.S. *Neptune* in an Admiralty Casualty List published on July 17. He was educated at the Anderson and St. Mungo's Colleges, Glasgow, and took the L.D.S. in 1938 and the Scottish triple qualification as a medical practitioner two years later. He entered the R.N.V.R. as prob. temp. surg. lieut. in March, 1941. His home was at Lhanbryde, Morayshire. He was a member of the B.M.A.

Temp. Surg. Lieut. **Eric Beresford Riding**, R.N.V.R., is reported "Missing, Presumed Killed" in H.M.S. *Neptune* in an Admiralty Casualty List published on July 17. He was educated at the University of Liverpool and graduated M.B., Ch.B. in 1938. After holding a post at the David Lewis Northern Hospital, Liverpool, he took an appointment as ship surgeon with the Holt Line in September, 1939, and entered the R.N.V.R. as prob. temp. surg. lieut. in February, 1941. His home was at Ormskirk. He was a member of the B.M.A.

Wounded.—War Subs. Capt. J. McD. Dougan, M.C., R.A.M.C.

Missing.—Capt. J. A. Falk, R.A.M.C., Major A. C. Glendinning, I.M.S., Capt. W. O. James, R.A.M.C., Col. G. P. Kidd, M.C., R.A.M.C., Major J. Parkes, R.A.M.C., Capt. N. C. Rogers, R.A.M.C., attached R.T.R.

DEATHS IN THE SERVICES

Surgeon Rear-Admiral **Arthur Richard Harrie Skey**, R.N. (retired), of Fareham, Hants, died in the Royal Naval Hospital, Haslar, on July 15. He was educated at Bart's, took the M.R.C.S., L.R.C.P. in 1896, and the M.B., B.S.Lond. in the same year. Entering the Navy soon after, he attained the rank of surgeon rear-admiral on July 1, 1927. He served in the war of 1914-18, receiving the medals.

EPIDEMIOLOGICAL NOTES

Discussion of Table

In *England and Wales* the numbers of notifications of scarlet fever and dysentery increased by 261 and 43, while the incidence of whooping-cough, diphtheria, measles, and acute pneumonia declined by 95, 76, 311, and 109 respectively when compared with the preceding week.

The 1,558 cases of scarlet fever constituted the largest weekly total since 1940. An increased incidence was common throughout the country and no large fluctuations were reported. The largest increases were those of London 29, Lancashire 23, Middlesex 22, and Somerset 21.

An outbreak of dysentery in Derbyshire with 86 cases was responsible for the increase in this disease. The distribution of the cases in the county was Staveley U.D. 32, Bolsover U.D. 4, Clowne R.D. 43, Chesterfield R.D. 6, Blackwell R.D. 1. Only 4 further cases were reported from the outbreak in Cumberland, Penrith M.B., making a total of 166 cases in four weeks. Of the 17 cases notified in London, 9 were in the borough of Wandsworth. The largest totals in the other administrative areas were those of Buckinghamshire, Aylesbury M.B. 5; Norfolk, Norwich C.B. 6; Staffordshire, Brownhills U.D. 9; Denbighshire, Wrexham R.D. 7; Pembrokeshire, Pembroke M.B. 8.

The notifications of acute poliomyelitis, 16 cases, were 11 more than in the preceding week. The cases were distributed through eleven counties, the only multiple cases occurring in Durham, Consett U.D. 2, and Warwickshire, Nuneaton M.B. 4.

For *Scotland* the feature of the returns was the increase in the incidence of dysentery; an outbreak involving 28 cases was reported from Banff County.

Small-pox

The number of fatal cases in the Glasgow epidemic rose to 8 with a death on July 29. No further cases have been reported for some days and the raising of the ban on hospital visitors is being considered. A case of small-pox has been reported in the London borough of Westminster. The patient was a Glasgow contact.

Returns for the Week Ending July 25

The notifications of infectious diseases during the week in England and Wales included: scarlet fever 1,516, whooping-cough 1,125, diphtheria 710, measles 6,817, pneumonia 479, cerebrospinal fever 89, acute poliomyelitis 12, dysentery 101, paratyphoid 11, typhoid 10.

No. 28

INFECTIOUS DISEASES AND VITAL STATISTICS

We print below a summary of Infectious Diseases and Vital Statistics in the British Isles during the week ended July 18.

Figures of Principal Notifiable Diseases for the week and those for the corresponding week last year, for: (a) England and Wales (London included). (b) London (administrative county). (c) Scotland. (d) Eire. (e) Northern Ireland.

Figures of Births and Deaths, and of Deaths recorded under each infectious disease, are for (a) The 126 great towns in England and Wales (including London). (b) London (administrative county). (c) The 16 principal towns in Scotland. (d) The 13 principal towns in Eire. (e) The 10 principal towns in Northern Ireland.

A dash — denotes no cases; a blank space denotes disease not notifiable or no return available.

Disease	1942					1941 (Corresponding Week)

* Includes primary form for England and Wales, London (administrative county), and Northern Ireland.

† Owing to evacuation schemes and other movements of population, birth and death rates for Northern Ireland are no longer available.

Medical News

New regulations issued by the Ministry of Health, to be known as the Public Health (Tuberculosis) Regulations, 1942, require medical officers of health to supply local offices of the Ministry of Labour with certain particulars of any women called before medical boards who are suffering or have suffered from tuberculosis. The procedure to be followed, which is different in some respects from that laid down for men, is set out in Circular 2648, which accompanies the regulations.

The minutes of the meeting of the Bombay Medical Council held under the presidency of Major-General R. H. Candy, C.I.E., K.H.S., on February 23 have been received in this country. This was the last meeting before the expiry of the term of the present council members at which General Candy presided, and a resolution was carried with acclamation placing on record the Council's high appreciation of the valuable services rendered by him as president, of the cordial manner in which he had conducted its deliberations, and of the courtesy, great ability, and zeal shown by him in handling the Council's affairs.

Sir Arthur J. Hall, M.D., F.R.C.P., having resigned the post of honorary consultant physician at Rampton State Institution, near Retford, Nottinghamshire, the Board of Control, with the approval of the Minister of Health, has appointed Dr. C. Gray Imrie, F.R.C.P., as his successor.

Prof. J. W. H. Eyre, M.D., has been elected President of the Royal Institute of Public Health and Hygiene in succession to the late Sir Thomas Oliver. He was senior vice-president and one of the founders in 1903 of the Institute of Hygiene, which amalgamated in 1937 with the Royal Institute of Public Health to form the present Institute.

The May issue of the *Boletin de la Oficina Sanitaria Panamericana*, which is dedicated to the eighth Pan-American Congress of the Child, contains articles on infant mortality in Costa Rica, the Child Health Department in El Salvador, infant protection in Mexico, physical education in Chile, and child nutrition in Latin America.

Letters, Notes, and Answers

All communications in regard to editorial business should be addressed to THE EDITOR, BRITISH MEDICAL JOURNAL, B.M.A. HOUSE, TAVISTOCK SQUARE, LONDON, W.C.1.

ORIGINAL ARTICLES AND LETTERS forwarded for publication are understood to be offered to the *British Medical Journal* alone unless the contrary be stated.

Authors desiring REPRINTS should communicate with the Secretary of the Journal Board, B.M.A. House, Tavistock Square, W.C.1, on receipt of proofs. Authors over-seas should indicate on MSS. if reprints are required, as proofs are not sent abroad.

ADVERTISEMENTS should be addressed to the Advertisement Manager (hours 9 a.m. to 5 p.m.). Orders for copies of the *Journal* and subscriptions should be sent to the Secretary.

TELEPHONE NO.—B.M A. and *B.M J.*: EUSTON 2111.

TELEGRAPHIC ADDRESSES.—EDITOR, *Aitiology Westcent, London*; SECRETARY, *Medisecra Westcent, London*.

B.M.A. SCOTTISH OFFICE: 7, Drumsheugh Gardens, Edinburgh.

QUERIES AND ANSWERS

Adder Bites

Prof. RENDLE SHORT (Bristol) writes in reply to Dr. Walker: No doubt many rural practitioners have seen a number of cases of this accident and can give a better account of it than I. In a recent case under my care, in a child who was bitten on the foot, the leg was very swollen and blue up to the groin for about three weeks, but the child did not seem much distressed. The bite had been excised and the wound treated with permanganate crystals within a few hours of the accident. A medical student who used to hunt adders in Somerset told me that he had been bitten on several occasions, and that after the first the bite gave very little trouble. I believe this is a well-known fact.

Coltsfoot

Dr. CONOR MAGUIRE writes from Claremorris: In reply to "Tussilago" (July 4, p. 30), William Woodville, M.D., *Medical Botany*, 1810, says: "The leaves have always been of great fame as possessing demulcent and pectoral virtues, useful in pulmonary consumption, coughs, asthma, and in various catarrhal symptoms. A valuable medicine in scrofula. It may be used as tea or given in the way of infusion, to which liquorice root or honey may be a useful addition. Smoking of the plant is recommended by Dioscorides, Galen, Pliny, and Boyle." He does not give any information about the curing of the plant.

LETTERS, NOTES, ETC.

Treatment of Scabies

Dr. E. M. BROCKBANK writes: In the 1914-18 war Manchester doctors serving with the Russian A.M.C. found that scabies was being regularly treated there by unguentum Wilkinsonii. This was a preparation in the Manchester Infirmary Pharmacopoeia of 1896 of Dr. A. T. Wilkinson (now consulting physician to the Infirmary). It consisted of equal parts of the *B.P.* sulphur, ammoniated mercury, and zinc oxide ointments, all of which then had benzoated lard as a base. The lard was looked upon as an effective constituent of the mixture. The benzoin prevented the lard from going rancid, and the 3% of it may have had some helpful antiseptic action. In Russia the ointment was applied three times in a week after preliminary soap and hot water preparation. In view of the more or less unsuccessful remedies now being used, it might be worth while giving the old-established one another trial in the present epidemic

Disinfecting Thermometers, etc.

Dr. WILLIAM SCOTLAND (Birmingham) writes: During over twenty years' experience of assistants and locumtenents in general practice I find that almost invariably thermometers are sterilized by soaking in a suitable solution, but are then *popped back into their soiled cases* So also with syringes: the actual syringe is carefully boiled but is put back into a soiled case. My routine advice is to carry half a dozen thermometers, soak them in a suitable antiseptic solution overnight, and boil the cases in the morning. Thus a soiled thermometer need never be used on any patient. Syringes *and their cases* should be boiled. As for ear, nose, and throat diagnostic sets, the specula rest in a velvet-lined nest. This shows that the manufacturers have little idea of the needs of the G.P. They do not appreciate that these portable sets are used as such in the patients' homes, and that there is frequently neither the time nor the convenience for sterilization immediately after use. There ought to be a boilable metal case to hold these parts, and a spare case to hold soiled ones until they can be disinfected at the surgery. I have advised more than one maker to redesign his "jewel case" on these lines, but with no result. So far as I am aware there is not one such on the market. All this is exceedingly elementary and very obvious, but unfortunately the obvious is too often missed.

We have recently received the price list of the medical products issued by British Drug Houses Ltd. (Graham Street, City Road, N.1). The products are arranged in alphabetical order, and the name of each product is followed by a description, indications for use, administration and dosage, modes of issue, and price to the medical profession. We are asked to state that the list will be sent, post paid, on request to any medical man.

MEDICINE 100 YEARS AGO

Extract from the *Provincial Medical Journal* for August 6, 1842:

"On the night of June 27, 1839, W.D., Esq., banker, in Douglas, aged fifty-two, was suddenly attacked with total blindness. He sent for me about two, a.m., of the 28th, when I found him sitting up in bed, straining and rolling about his eyes in search of the light. The pupils of both eyes were much dilated, and looked darker and more brilliant than usual. He felt no pain, except a slight uneasiness across the eyes and forehead, and along the nose. Upon a lighted candle being held close to the eye, he said he was sensible of nothing but 'total darkness' Skin cool and natural, pulse not accelerated, but rather full; tongue white and loaded; manner composed, and mind collected. . . . I immediately took upwards of a pound of blood from the arm, administered six grains of calomel and six of scammony, and directed the patient to use a hot mustard bath for the lower extremities as soon as possible, and a stimulating application of tincture of camphor and sulphuric aether to the forehead and temples. Six hours afterwards, when his bowels had been evacuated by the purgative, an emetic mixture, containing the tartarised antimony and ipecacuanha, was exhibited, which, being slow in operating, a teaspoonful of powdered mustard was administered with excellent effect. At mid-day, 28th of June, ten leeches were applied to the temples, and the calomel and scammony were repeated soon after, with directions to assist their operation by a dose of castor oil in the evening if necessary. By these means the primae viae were well cleared out the first day of the attack; and as my patient complained much of thirst and nausea, and foulness of the mouth and palate, effervescing draughts, made of the volatile alkali and citric acid, were prescribed to be taken every hour, in order to obviate the necessity of loading the stomach with much liquid, and to mitigate the febrile heat of the surface, which set in towards evening of the first day." Passages from an article by Henry Oswald, F.A.S E., etc., on "A Case of Amaurosis successfully treated."

THE ROLE OF RENIN IN EXPERIMENTAL HYPERTENSION

BY

B. A. HOUSSAY

AND

E. BRAUN-MENENDEZ

(From the Institute of Physiology, Faculty of Medical Sciences, University of Buenos Aires)

In 1934 Goldblatt and others discovered that partial constriction of the main renal artery produces a marked and permanent hypertension in the dog. The renal experimental hypertension caused by this or other methods in laboratory animals is similar in many respects to human essential hypertension. It is not due to excretory insufficiency of the kidney or to an increase of blood volume or cardiac output, nor is it produced through a nervous mechanism. Houssay and Fasciolo (1937a, 1937b) have shown that renal ischaemia results in hypertension through a humoral mechanism. The ischaemic kidneys of dogs with chronic hypertension were grafted into the neck of normal or nephrectomized dogs. The arterial pressure of the recipient dog rose from 30 to 80 mm. Hg in 5 to 10 minutes, while grafting a normal kidney had no such effect. The citrated plasma obtained from the veins of these ischaemic kidneys produced vasoconstriction when perfused through a Läwen-Trendelenburg preparation; normal plasma had no vasoconstrictor action (Houssay and Taquini, 1938).

Braun-Menendez and Fasciolo (1939a, 1939b) made the observation that acute partial ischaemia of the kidneys produced the same effects as chronic ischaemia: (1) if the artery of a normal kidney grafted into the neck of a dog was constricted a slight but definite increase in blood pressure was produced; (2) the blood of acutely ischaemic kidneys when injected intravenously into anaesthetized dogs produced greater increases in blood pressure than control blood; and (3) it had a vasoconstrictor action on the Läwen-Trendelenburg preparation. Braun-Menendez, Fasciolo, Leloir, and Muñoz (1939) prepared extracts from the venous blood of these kidneys and discovered a pressor substance which was named "hypertensin." They found that this substance could also be prepared *in vitro* by incubating at 37° C. blood plasma or serum with renin, a protein which is present in extracts of kidney (Braun-Menendez, Fasciolo, Leloir, and Muñoz, 1940a). It was also shown that renin is secreted by the ischaemic kidney and hypertensin is formed subsequently in the venous blood.

Our present knowledge on the mechanism of renal hypertension might be summarized as follows: The ischaemic kidney secretes renin. This protein is an enzyme which acts on a blood globulin (hypertensinogen) and gives rise to a substance (hypertensin) that has a direct vasoconstrictor action. Another enzyme, hypertensinase, which destroys hypertensin, is present in blood and tissues.

Some Properties of Renin.—In 1898 Tigerstedt and Bergman discovered that kidney extracts contained a pressor substance —renin. This substance is a protein, probably a globulin, and is inactivated by heat at 60° C. Its intravenous injection produces in the dog a gradual rise in blood pressure which lasts 10 to 30 minutes, depending on the dose. Consecutive injections of large doses at short intervals produce each time a smaller response. This phenomenon is called "tachyphylaxis," and was originally described by Tigerstedt and Bergman. Renin by itself is neither vasoconstrictor nor vasopressor; these properties are due to the hypertensin formed by the action of renin on hypertensinogen.

Methods for the Estimation of Renin.—Two general methods can be used for the detection and estimation of renin. The first consists in comparing the rise in blood pressure caused by the injection of an extract or body fluid containing renin with that of a standard solution of renin. The second is based on the formation of hypertensin when renin is mixed with hypertensinogen. The hypertensin formed can be tested for its vasoconstrictor (Page, 1940) or pressor action (Leloir, Muñoz, Braun-Menendez, and Fasciolo, 1940b). The latter method (Leloir and others 1940a, 1940b), more reliable, has been used almost exclusively in our laboratory. This method is specific for renin, very sensitive, and quantitative within the limits of a bio-assay method. A unit of renin is the amount which, incubated for 2 hours at 37° C. with an excess of hypertensinogen, forms 0.5 unit of hypertensin. Applying these methods, it has been shown that renin is liberated:

1. By Totally Ischaemic Kidneys.—The re-establishment of the renal circulation of the kidney *in situ* after total ischaemia lasting 2 to 6 hours causes a rise in arterial pressure similar to that produced by an injection of renin. The venous blood of these kidneys has pressor and vasoconstrictor properties. Using the quantitative method of Leloir and his colleagues, it has been shown (Taquini and Braun-Menendez, 1941) that very large amounts of renin may be liberated by the kidney under these conditions.

2. By Ischaemic Kidneys of Hypertensive Dogs.—If the ischaemic kidney of a hypertensive dog is grafted into the neck of a normal dog a rise in blood pressure is produced similar to that produced by the injection of a small amount of renin (Fasciolo, Houssay, and Taquini, 1938). The venous blood of these kidneys has vasoconstrictor properties (Fasciolo, Houssay, and Taquini, 1938). Using the quantitative method of Leloir and his colleagues, renin was estimated in the renal venous blood of kidneys transplanted under the skin (Dell'Oro and Braun-Menendez, to be published). No renin was present in normal conditions, but after constriction of the renal artery, and coincident with the increase of blood pressure, variable amounts of renin (from 0.8 to 1.2 units per 12 c.cm. of plasma) were found in the renal venous blood and in the femoral blood of these dogs. All these results justify the conclusion that the ischaemic kidneys of dogs with experimental hypertension secrete renin into the blood.

3. By Kidneys in Acute Partial Ischaemia.—It has already been mentioned that a few minutes after partial constriction of the renal arteries renin can be detected in the venous blood of these kidneys.

4258

Secretion of Renin by the Normal Kidney.—Apart from ischaemia due to constriction of the renal artery, are there other conditions which result in the secretion of renin by the kidney? Huidobro and Braun-Menendez (investigations to be published) have shown that hypotension due to haemorrhage or shock causes the liberation of renin by the intact kidney of normal anaesthetized dogs. Renin was detected and estimated in the systemic blood of these dogs. The inference is drawn that the kidney participates in the regulation of arterial blood pressure. When the blood pressure decreases the normal kidney secretes renin, which through the formation of hypertensin tends to the restoration of normal blood pressure. Renin appears to be a substance which the body uses to maintain homeostasis. Collins and Hamilton (1942) and Sapirstein, Ogden, and Southard (1941) have arrived independently at the same conclusions.

Formation and Mode of Action of Hypertensin

Enzymatic Action of Renin (Munoz et al., 1940)

The formation of hypertensin *in vitro* or *in vivo* is the result of an enzymatic reaction in which the substrate is a blood globulin that we have called "hypertensinogen," and the enzyme is renin. This affirmation is based on the following facts: (1) Renin is a protein: its activity is destroyed by heating (60° to 80° C.) and delayed or abolished at low temperatures. (2) The reaction between renin and hypertensinogen has a temperature optimum of 37° to 45° C. and a *p*H optimum of 7.5 to 8.5. (3) The yield of hypertensin is proportional to the amount of globulins. (4) If the amount of renin exceeds the optimum the maximum yield of hypertensin is not surpassed if 10 to 20 times more renin is used. (5) The time necessary for obtaining the maximum yield of hypertensin, or, in other words, the velocity of the reaction, depends on the amount of renin. (6) Hypertensinogen disappears in the reaction while renin does not.

This is the evidence which supports our assertion that renin is an enzyme. As the substrate on which renin acts is a protein, and the product of reaction is, as we shall see, probably a polypeptide, it is reasonable to classify renin as a proteolytic enzyme.

Specificity of Renin

Renin may be defined as the substance contained in kidney extracts which, when incubated with blood globulins, gives rise to hypertensin. Extracts of other organs—liver, spleen, placenta, etc.—do not contain renin. Recently Croxatto and Croxatto (1941) demonstrated that by the action of pepsin on hypertensinogen a vasoconstrictor and pressor substance is formed, the properties of which resemble those of hypertensin. These results, which have been confirmed by ourselves and by Helmer and Page (1942), constitute strong indirect evidence in favour of the enzymatic action of renin.

Renin has been found in human kidneys and in the kidneys of every mammal which has been investigated—ox, horse, dog, pig, sheep, goat, rat, rabbit, guinea-pig, etc. The incubation of renin from these animals with plasma from any of them gives rise to the formation of hypertensin. But no hypertensin is formed when any of those renins is incubated with human plasma. On the other hand, human renin is active on the plasma of any of those animals and also on human plasma. This peculiar specificity of renin led to the prediction that no pressor response should be obtained in man when pig's renin, for instance, is injected intravenously, while human renin should be active (Fasciolo, Leloir, Muñoz, and Braun-Menendez, 1940a). This prediction was verified by experiments (Battro and others, 1940). Bean (1942) found no renin in the kidneys of the species of fishes and amphibians studied by him. He found renin in the kidneys of fowl and duck which acted exclusively on blood belonging to the same class.

Hypertensinogen

Hypertensinogen, the substrate of renin in the reaction which leads to the formation of hypertensin, can be prepared from blood plasma or serum by fractional precipitation with ammonium sulphate or potassium phosphate. It is a globulin, probably a euglobulin, and is inactivated by heat at 60° C.

Attempts to obtain hypertensinogen from other sources than blood serum have failed: liver, spleen, thymus, testes, lungs, heart or skeletal muscle, milk and egg proteins, haemoglobin, serum albumin, and some vegetable proteins did not yield hypertensin when incubated with renin (Muñoz, Braun-Menendez, Fasciolo, and Leloir, 1940). Hypertensinogen can be estimated in blood samples by the maximum amount of hypertensin it produces. A unit of hypertensinogen is that which gives rise to one unit of hypertensin under the conditions outlined.

Hypertensin

This substance, which was discovered in the venous blood of ischaemic kidneys, is the product of the enzymatic reaction between renin and hypertensinogen.

In 1938 Kohlstaedt, Helmer, and Page showed that purified preparations of renin produced no vasoconstriction when perfused with Ringer's solution through a dog's tail or rabbit's ear, but that the vasoconstrictor activity could be restored by the addition of a protein-like substance contained in blood. They designated this substance renin-activator to connote that renin was inactive as a vasoconstrictor substance without it. Subsequently they found (Page and Helmer, 1940) that from the interaction of these two substances a new substance resulted with potent vasoconstrictor and pressor actions which they called "angiotonin." It is interesting how, coming in two different ways—the Indianapolis group via the purification of renin, and that of Buenos Aires via isolation of the active substance in the venous blood of ischaemic kidneys—both groups arrived independently and simultaneously at the discovery of the substance which results from the interaction of renin and blood.

Hypertensin is very soluble in water, insoluble in ether, thermostable, and acid-resistant. In NaOH 0.15 at 100° C. it is destroyed in 10 minutes. Kept in the cold store and free from contamination, hypertensin, dried or in solution, is stable. It can be salted out by ammonium sulphate. It dialyses through cellophane. It is inactivated by incubation with pepsin and trypsin. Although Page and Helmer report that the biuret reaction is negative, the inactivation by pepsin would indicate that it is a polypeptide. Some of its chemical and physical properties (velocity of diffusion) and its proteic origin are in favour of this idea. We have not been able to obtain a pure product, and this has compelled us to adopt an arbitrary unit in order to compare the pressor action of different solutions of hypertensin. A unit of hypertensin is the amount necessary, when given intravenously, to raise the arterial pressure of a 10-kg. chloralosed dog an average of 30 mm. Hg. A standard solution was prepared which has 1 unit per c.cm.

Hypertensin does not cause tachyphylaxis. When the dose is increased the rises in pressure in mm. Hg increase as the square root of the units injected, according to the formula $X = St\sqrt{y}$, in which X and St are the blood-pressure increases in mm. Hg obtained by the unknown and by 1 c.cm. of the standard solution respectively, and y the units of hypertensin contained in the unknown (Braun-Menendez, Fasciolo, Leloir, and Muñoz, 1940b).

The Pressor Action of Renin

There is strong evidence that the action of renin *in vivo* is due to the hypertensin formed by its action on hypertensinogen:

(1) The perfusion of renin in Ringer's solution through a vascular system does not produce vasoconstriction; but if mixed with blood globulins and perfused after short incubation, marked vasoconstriction results, due to the hypertensin formed. (2) The prolonged pressor action of injected renin may be explained by the continuous formation of hypertensin: a similar pressor effect is produced by the continuous intravenous infusion of hypertensin. (3) When renin does not form hypertensin *in vitro* it has no pressor action *in vivo*. For instance, pig renin, which does not give rise to hypertensin when incubated with human serum, does not produce a pressure increase when injected intravenously into human beings. (4) The pressor action of renin is greater when the concentration of hypertensinogen in blood is increased (dogs nephrectomized 48 hours previously) and smaller when decreased (adrenal insufficiency) or exhausted (by repeated injections of renin). (5) The pharmacological actions of renin and hypertensin are identical when injected into the animal, and are influenced in the same way by diverse drugs: no change of action by

Fourneau 933, cocaine, atropine, ergotamine, etc.; potentiation by veritol or ephetonine (Braun-Menendez, Fasciolo, Leloir, and Muñoz, 1940b).

The pressor action which renin exerts through the formation of hypertensin is perhaps not the exclusive mechanism in renal hypertension. It is very possible that other phenomena play their part. Perhaps also, after hypertension is initiated by renin, some changes occur in the body which contribute to maintain the elevated blood pressure, or vice versa.

Treatment of Renal Hypertension

The better understanding of the mechanism of renal hypertension may give us some indications as to the possibilities of a specific treatment. This should aim at (Muñoz, Braun-Menendez, Fasciolo, and Leloir, 1940): (A) suppressing or diminishing the secretion of renin; (B) destroying the renin secreted by the ischaemic kidney or inhibiting its reaction with blood globulins; (C) diminishing the amount of hypertensinogen; and (D) preventing the action of hypertensin by increasing the amount or the activity of hypertensinase or by some other mechanism.

(A) *Suppression or Diminution of the Secretion of Renin.*—In Goldblatt dogs, release of the constriction of the renal artery, removal of the clamp, or nephrectomy results in a drop to normal of the elevated blood pressure. In man the existence of hypertension with unilateral renal disease has been recognized. In many of these cases excision of the diseased kidney resulted in a return of blood pressure to normal with disappearance of other symptoms and complications. The development of collateral circulation in the ischaemic kidneys of Goldblatt dogs—whether spontaneous or promoted by decapsulation and implantation of omentum or spleen—results in a drop to normal of the elevated blood pressure. The promotion of collateral circulation has also been attempted in man by grafts of omentum or muscle in renal tissue with varying results.

(B) *Destroying the Renin secreted by the Ischaemic Kidney.*—It has been shown, first by Fasciolo (1938) and then by others, that the normal kidney exerts some sort of protective action against hypertension of renal origin. Grollman, Williams, and Harrison (1940) on a basis of indirect evidence believed that this action was due to an antipressor substance secreted by the normal kidney. They injected extracts of kidney to hypertensive rats and dogs, and obtained a decline in blood pressure. These extracts were active even on oral administration. Page and co-workers (1941) have also prepared different kinds of extracts of kidney, muscle, and lung which, when injected into dogs or rats with experimental hypertension, caused the blood pressure to fall to normal levels. They have obtained the same results in human beings with malignant hypertension. These studies are very important and promising, but for the moment it cannot be stated whether those extracts contain specific neutralizing or antipressor substances or whether their benefit arises from the introduction of non-specific foreign elements into the body. The attempts of Wakerlin and Johnson (1941) to neutralize the action of renin by immunological means have apparently been unsuccessful. Schroeder and Adams (1941) reduced the blood pressure of hypertensive human beings, rats, and dogs by the injection of tyrosinase. They reported that this enzyme inactivates renin *in vitro* in the presence of catechol and hypertensin in the presence of serum. Further evidence is necessary to judge these results.

(C) *Diminution of the Amount of Hypertensinogen.*—Very little, if anything, is known about the exact nature of hypertensinogen, its site of formation, etc. It is nevertheless theoretically possible to lower the blood pressure in renal hypertension by diminishing the amount of hypertensinogen. For the moment we know of only one way to obtain this result—that is, by the injection of large amounts of renin.

(D) *Increase of the Amount of Hypertensinase.*—Serum, plasma, or red cells, and extracts of many organs (kidney, liver, spleen, etc.) are active in destroying hypertensin, owing to the presence of a substance which we have designated "hypertensinase." This substance is destroyed by heating and has a *p*H optimum between 7.5 and 8.5. It can therefore be considered as an enzyme. Its action is not suppressed by anaerobiosis, cyanide, octyl alcohol, chloroform, thymol, toluol, fluoride, iodo-acetate, pyrogallol, etc. It is precipitated with ammonium sulphate between 0.3 and 0.6 saturation. It is inactivated in 20 minutes at 25° C. at *p*H 3.9. A unit of hypertensinase is the amount which destroys 0.5 unit of hypertensin in 4 hours in a volume of 10 c.cm. with an initial concentration of 1 unit of hypertensin (Fasciolo, Leloir, Muñoz, and Braun-Menendez, 1940b). Fasciolo and others (1940a, 1940b) have studied the distribution of hypertensinase in saline extracts of different organs. The highest content was found in the kidney and intestinal mucosa, the lowest in plasma or serum. Haemolysed blood cells contain a large amount of hypertensinase. We have made some preliminary essays injecting kidney and liver extracts rich in hypertensinase into hypertensive dogs. The results, though promising, have not been very clear. The fact that hypertensinase is a most unstable substance renders difficult its isolation in tissue extracts. These difficulties have hampered progress in this direction. Page now ascribes the antipressor action of his renal extracts to the presence in them of hypertensinase.

Conclusion

We believe that the therapeutic problem of renal hypertension has not yet been solved; but we are confident that the solution will be attained by a patient and thorough investigation of the underlying mechanisms which are involved in the production of renal experimental and human hypertension. In spite of the enormous progress of the past few years we still know very little about them. Let us hope that in the near future research will give medicine a new and powerful weapon to fight arterial hypertension, this most death-dealing malady to-day.

H. D. Hahn (*Amer. J. Syph. Gon. ven. Dis.*, 1941, **25**, 200) reviews the literature of second infection in congenital syphilis, and comes to the conclusion that up till now no indisputable second infection in a congenital syphilitic patient has been reported. He records, however, two personal cases of reinfection in adequately treated congenital syphilis. In the first case there were thirteen years of clinical and serological negativity between the congenital and the acquired infection. In the second, though the serological test for syphilis never became entirely negative, there were at least eight years of clinical negativity, including a negative cerebrospinal fluid between the congenital and the acquired infection.

THE DISINFECTANT ACTION OF PHENOL AND OF ALCOHOL IN T.A.B.C. VACCINE*

BY

JOHN C. CRUICKSHANK, M.B., Ch.B. D.T.M., Dip.Bact.

BETTY C. HOBBS, B.Sc., Ph.D., Dip.Bact.

ALLAN M. McFARLAN, M.A., M.B., B.Ch.

AND

IRENE MAIER

The substitution by Felix (1941) of alcohol for phenol in T.A.B.C. vaccine in order to prevent destruction of the Vi antigen represents a considerable advance in the method of prophylactic inoculation against enteric fever. The alcohol, which was employed in a 22.5% or 25% concentration, was intended to fulfil the double purpose of preserving the activity of the Vi antigen and of guarding against infection by virtue of its antiseptic properties. Doubts, however, were soon raised as to its efficiency in this latter respect. Since Felix in his study of the bactericidal action of this substance worked with only one organism, *Staph. aureus*, and since he gave no protocols of any of his experiments, it was felt that the only satisfactory way of allaying these doubts was to carry out a series of observations in which the destructive effect of different strengths of alcohol on different organisms was compared with that of 0.5% phenol.

Technique

Four constituent laboratories of the Emergency Public Health Laboratory Service took part in these trials. Bottles containing 25 ml. of the following T.A.B.C. vaccines were distributed to each laboratory: (*a*) 0.5% phenol, Batch 18, Oct., 1940, prepared by the Lister Institute; (*b*) 22.5% alcohol, Batch A1, Sept., 1940, prepared by the Lister Institute; (*c*) 25% alcohol, Batch AA4, May, 1940, prepared by Dr. Felix.

The experiments were carried out during the summer and autumn of 1941. Observations were made on *Staph. aureus, Bact. coli, Ps. pyocyanea*, and, in three laboratories, on the spores of *B. subtilis* and *Cl. sporogenes*. With a few exceptions different strains of these organisms were used by different laboratories. The general plan of the experiments was as follows. The three species of non-sporing organisms were grown overnight on agar; the growth was washed off with quarter-strength Ringer solution and standardized by opacity. Equal amounts of suspension were then inoculated into each of the three vaccines. The mixtures were left at laboratory temperature, and samples were withdrawn at intervals and counted by the roll-tube or plate method. Tests with the sporing organisms were made in a similar manner, except that spore suspensions were used in which there were very few vegetative bacteria, or in which the vegetative bacteria had been killed by heat.

The technique used in the individual laboratories differed, however, in several respects. In one laboratory 10-ml. quantities of each vaccine were transferred to fresh sterile bottles and an inoculum of 0.1 ml. was added by a micrometer syringe; the exact quantity of the vaccine was thus known, and the dilution of the disinfectant was only 1%. In other laboratories the amount of vaccine in each bottle was not measured, so that minor variations from the supposed 25 ml. were almost certainly present, and the inoculum, which was added by a pipette or syringe, ranged from 0.25 to 0.5 ml., thus leading to a maximum dilution of the disinfectant of 2%. In three laboratories a viable count was made on the inoculum itself; in one laboratory the initial count was made on the vaccine immediately after the addition of the inoculum. The number of organisms inoculated varied from a few thousand to several millions per ml. of vaccine. The subsequent counts were made at different times in different laboratories. In one laboratory one count was made after 2 hours and another after 24 hours; in the others several counts were made within the first few hours and one after 24 hours. The temperature to which the organisms were exposed varied in different laboratories.

Assessment of Results

With so many variations in technique in different laboratories analysis of the results obtained presented great difficulty. Reproduction of the individual protocols is impossible by reason of space. Preliminary examination of the data showed that in many of the experiments the number of the counts was too few or their distribution too uneven to justify comparison by means of the reaction velocity constant, or by the method recently advocated by Withell (1942) of estimating the time taken to destroy 50% of the organisms. On the whole the best method seemed to be to work out the geometric mean of each series of counts. In doing this the initial count and the final count, if all three vaccines were sterile, were omitted, and the arithmetic mean of the logarithms of the remaining counts was calculated. Table I illustrates the use of this method.

TABLE I.—*Exposure of Ps. pyocyanea to Alcohol and to Phenol, showing Number of Organisms surviving after Different Times. Inoculum was 7,900 Organisms per ml. (Experiment 18 of Table II.)*

Time in Minutes	25% Alcohol		0·5% Phenol		22 5% Alcohol	
	Nos.	Log. of Nos.	Nos.	Log. of Nos.	Nos.	Log. of Nos.
20	2,280	3·3579	6,500	3·8129	3,740	3·5729
40	372	2·5705	5,000	3·6990	2,240	3·3502
80	12	1·0792	2,500	3·3979	1,660	3·2201
135	3	0·4771	160	2·2041	1,460	3·1644
255	0	0·0000	0	0·0000	672	2·8274
390	0	0·0000	0	0·0000	56	1·7482
Total		7·4847		13·1139		17·8832
A.M. of logs		1·2475		2·1857		2·9805
G.M.	18		153		956	

A.M. = Arithmetic mean. G.M. = Geometric mean. The 22·5% alcohol suspension was sterile after 24 hours

The true sterilization time was not available, but the time at which the first sterile count was recorded was used as a rough index for comparing the activity of the three disinfectants in any one experiment.

Results

In none of the laboratories was evidence obtained to show that the strengths of the two disinfectants used had any destructive effect on the spores of *B. subtilis* or *Cl. sporogenes* within 24 hours. No further description of the results is therefore called for.

Twenty comparative experiments were made on *Staph. aureus, Bact. coli*, and *Ps. pyocyanea*. An illustrative protocol has already been given in Table I. A summary of all the experiments is provided by Table II. It will be seen that except for experiments 6 and 19, in which two or all three of the vaccines were sterile at the time of the first count, the geometric mean was least in the 25% and greatest in the 22.5% alcoholized vaccine, the count in the 0.5% phenolized vaccine occupying an intermediate position. Similarly in all the experiments in which the results could be compared, the 25% alcoholized vaccine became sterile first and the 22.5% alcoholized vaccine last. There seems, therefore, no reason to doubt the order of bactericidal potency of these three substances, though our data are not complete enough to enable us to state how much superior 25% alcohol is to 0.5% phenol, or 0.5% phenol is to 22.5% alcohol.

It will, however, be noted that even with very large inocula —far greater than would be likely to occur in practice as the result of using an imperfectly sterilized needle with which to withdraw vaccine from the bottle—there were only three experiments with the 22.5% alcoholized vaccine in which organisms were alive at the end of 24 hours. In experiments 4 and 11 the numbers of surviving organisms were 79 and 19 per ml. respectively. In experiment 8, with an inoculum of 9,000,000 per ml., the 24-hour count in the 22.5% alcoholized vaccine was 198,000 and in the 0.5% phenolized vaccine 9,800 per ml. In experiment 5 a 24-hour count was not made, but as the count at 7½ hours was only 8 per ml. there is every reason to believe that the vaccine would have been sterile within 24 hours.

---

* A report to the Medical Research Council from the Emergency Public Health Laboratories at Exeter, Cardiff, Oxford, and Ipswich.

With small inocula it is probable that sterility would be achieved with 22.5% alcohol in a time not very much longer than with 0.5% phenol. This supposition is supported by the finding of Dr. Carruthers at Cambridge that, with an initial inoculum of 80 to 150 organisms per ml., *Staph. aureus, Bact. coli,* and *Ps. pyocyanea* were destroyed by 25% alcohol within 15 minutes, by 0.5% phenol within 2 hours, and by 22.5% alcohol within 4 hours.

Laboratory C performed control experiments by inoculating along with each set of three vaccines a fourth bottle of heat-killed T.A.B.C. vaccine containing no disinfectant. In seven experiments the counts of the control vaccine at 2 and 24 hours did not differ from that of the inoculum by more than was to be expected from the sampling error of the technique, showing that no multiplication of the organisms had occurred. Even without any disinfectant, therefore, T.A.B.C. vaccine does not constitute a favourable medium for bacterial growth. The function of the added disinfectant is merely to deal with any organisms that may gain access to the bottle as the result of contamination. That 22.5% alcohol is capable of fulfilling this function there seems no reason to doubt.

Discussion

The experiments just described were undertaken in order to solve a specific practical problem, not to make an academic study of the reaction velocity and other constants of alcohol. For this reason only their general plan was laid down, each laboratory being left a considerable margin of freedom to decide on the detailed conduct of the experiments. That the four laboratories placed the three disinfectant solutions tested in the same order of potency is therefore all the more convincing.

The failure of alcohol to bring about any appreciable destruction of spores is in conformity with the observations of previous workers (for references see Coulthard and Sykes, 1936). Similarly, 0.5% phenol is known to be without effect on spores (Chick, 1908). Our results with spores therefore call for no comment.

With vegetative organisms, 22.5% and 25% alcohol and 0.5% phenol all proved to be moderately bactericidal. The order of potency, as determined by the four different laboratories using three different species of organism, was uniformly consistent, 25% alcohol proving the most and 22.5% alcohol proving the least bactericidal. The difference in killing power between the two strengths of alcohol was remarkable. It has been demonstrated by Minervini (1898) that the most germicidal concentration of alcohol is between 50% and 70%. Above and below this level its effect is less. Judging from the findings of Tilley (1939) that in the 26% to 34% range a decrease of 2% in concentration approximately doubled the time necessary for sterilization of *Bact. typhosum,* and from our observations that a fall from 25% to 22.5% produced an even greater effect, it seems clear that the slope of the curve depicting the germicidal potency of alcohol in the 20% to 35% range of concentration must be fairly steep.

So far as it is permissible to compare the rate of destruction of *Staph. aureus, Bact. coli,* and *Ps. pyocyanea,* our results showed little difference in the behaviour of these three organisms. Lockemann, Bär, and Totzeck (1941), on the other hand, found that *Staph. aureus* was considerably more resistant to all strengths of alcohol than either *Bact. coli* or *Ps. pyocyanea.*

Table II.—*Exposure of Different Vegetative Organisms to Alcohol and to Phenol*

Organism	No.	Laboratory	Approximate Temperature °C.	Inoculum : Organisms per ml. Vaccine	Geometric Means of Viable Counts per ml. Vaccine				*Time of First Sterile Sample in Hours		
					No. of Counts	25% Alcohol	0·5% Phenol	22·5% Alcohol	25% Alcohol	0·5% Phenol	22·5% Alcohol
Staph. aureus	1	D	25–6	1,000	4	7	18	400	4	4	24
	2	D	23–5	1,500	5	21	40	214	4	4	24

	13	C	21	298,000	1	0	1,010	1,030	2	24	24
	14	C	23	4,200,000	1	0	410	69,000	2	24	24
Ps pyocyanea	15	D	22–3	1,000	1	0	19	104	0·5	1	1
	16	B	—	1,500	3	1	3	70	0·5	0·5	2
	17	D	20–1	2,500	3	21	126	538	4	4	4
	18	A	20–2	7,900	6	18	153	956	4	4	24
	19	C	21–3	189,000	1	0	0	0	2	2	2
	20	C	21–3	11,700,000	1	63	2,400	57,000	24	24	24

Note.—Owing to the differences in the size of the inoculum and other conditions the figures should be compared only horizontally. It should also be noted that the times given in the last three columns are not true "sterilization times."

Summary

Four laboratories carried out experiments in which the disinfectant action of 22.5% and 25% alcohol was compared with that of 0.5% phenol in T.A.B.C. vaccine.

A few observations made on the spores of *B. subtilis* and *Cl. sporogenes* failed to reveal any bactericidal activity of the three vaccines.

Eight experiments were carried out with *Staph. aureus,* six with *Bact. coli,* and six with *Ps. pyocyanea,* in which known numbers of organisms were inoculated into each of the three vaccines and in which the survivors were estimated at varying intervals of time by the roll-tube or plate method of counting.

In every experiment in which the figures were suitable for comparison it was found that the organisms perished most rapidly in the 25% and least rapidly in the 22.5% alcoholized vaccine, the 0.5% phenolized vaccine occupying an intermediate position in this respect.

Reasons are given for believing that 22.5% alcohol is only slightly inferior to 0.5% phenol in its germicidal potency, and that it is capable of destroying within a few hours vegetative bacteria that may gain access to T.A.B.C. vaccine by contamination.

There is no ground for the fear that the 22.5% alcohol used in Felix's new vaccine is likely to prove inefficient as a preservative.

A MATERNITY SERVICE SCHEME*

BY

DAME LOUISE McILROY, M.D., F.R.C.P., F.R.C.O.G.

In opening a discussion on maternity services the starting-point must be the welfare of the patient and her wishes in the matter. A maternity service scheme must fit in with the general plan of a composite State medical or health service. With the establishment of the Royal College of Obstetricians and Gynaecologists, obstetrics takes its place on an equal footing with medicine and surgery and is not merely a special branch. It has had close collaboration with the public health services. The introduction of ante-natal care has given a much wider scope for the practice of preventive medicine, and teaching has expanded beyond the abnormalities of the bony pelvis and the positions of the foetus. The obstetrician now works in collaboration with the orthopaedic surgeon, the paediatrician, the cardiologist, and the tuberculosis specialist. The help of the pathologist and the radiologist is often required for accurate diagnosis, and much more time is now expended upon the clinical examination of the patient than formerly.

Social services also play a large part in the practice of midwifery. Institutional expenditure in other directions could be reduced if we could reduce or eliminate the blindness due to ophthalmia of the newborn. Mental deficiency due to injuries at birth could be lessened to some extent; also tuberculosis, if there were more provision for prolonged residence in sanatoria and facilities for childbirth in these institutions. With more efficient post-natal care the crippling effects of child-bearing upon women would also be lessened. Ante-natal care would lower the neonatal death rate due to prematurity, birth injuries, and malnutrition.

The Economic Aspect

The economic aspect of maternity practice is of the utmost importance to the State. In my opinion, infant welfare should be under the direction of the paediatricians after the first month of life. Gynaecology cannot be separated from obstetrics, as treatment is required for post-natal complications.

Much of the organization of the maternity services has been haphazard and lacking in co-ordination. This to some extent has been inevitable. New ideas and methods had to be tried out by voluntary organizations and proved of value before public funds could be utilized for anything approaching an experiment. Legislative reforms have brought about great advances in midwifery, such as the various Midwives Acts. Local authorities were given permission to make use of public funds for maternity and child welfare work. It might have been better if in some cases these powers had been made compulsory. The Local Government Act of 1929 made a great advance in the establishment of maternity beds in municipal and county hospitals. The London County Council is an outstanding example of this improvement. It is more satisfactory to have a maternity department in a large general hospital than in isolated units, with the exception of small maternity homes linked up with larger hospitals. In a general hospital auxiliary services are easily obtainable for consultative work, and there is economy of staff and equipment.

Defects in Present Maternity Services

In building up a scheme it is well to find out what is essential, what is deficient in existing schemes, and what should be avoided. In some areas under a keen medical officer of health the arrangements are excellent and the work with the local practitioners is harmonious. In others the standard of efficiency is low. Neonatal mortality on the whole has been very little reduced during the first twenty-four hours of life. For this the obstetrician must bear the responsibility. The chief defects in our present maternity services are the limited number of beds in industrial areas. Ante-natal and post-natal beds especially are very inadequate. Emergency cases in rural areas may have to be sent long distances because no beds are available and general hospitals may have little provision for maternity cases.

In the future it is probable that domiciliary midwifery will be still further reduced owing to the difficulties of housing and home service. Flats are unsuitable and are noisy, and women should not have their confinements in slum dwellings.

Rest from household cares and good nursing have a highly beneficial effect upon the nerves of women. These conditions are supplied by hospitals and local maternity homes. Since the war, residents in evacuation areas often are forced to have their confinements in overcrowded homes, as the local maternity homes are booked up for patients coming from cities and towns in more dangerous areas. Convalescent homes are also an important part of a scheme for maternity services, for ante-natal as well as for post-natal cases. Patients are sent out of hospital too soon in some cases owing to pressure upon the beds for childbirth.

Ante-natal clinics in connexion with maternity hospital staffs are satisfactory, as there is continuity of supervision throughout pregnancy and childbirth. In country and municipal ante-natal clinics, however, the assistant medical officer may have had little clinical experience of midwifery, his special qualification being the possession of a diploma in public health. The chances of promotion in such a service, for women especially, are small owing to lack of special training in administrative methods. Local authorities, however, are beginning to recognize this difficulty and to insist upon a diploma in midwifery. If complications arise during pregnancy the patient is sent either to hospital or to a local practitioner who may not be very much interested in her condition as she preferred to attend the clinic at the outset of the pregnancy. In cases where a midwife is in attendance at the confinement a local doctor is called in if any complication arises, and, with no personal knowledge of the patient's previous condition, he may criticize the treatment at the clinic. If the patient is seen later at the post-natal clinic, criticism may be made of the methods employed at childbirth. Midwives who do not work with a recognized team of practitioners serving on a midwifery rota find it not always possible to get help in an emergency, and delay may be serious for the patient concerned.

The fault lies in this practice of dual responsibility and absence of continuity of supervision. This may be illustrated by the proverb, "Never swap horses while crossing a stream."

In some areas, especially when at a distance from towns, the local practitioners should be chosen as a team because of their competence to practise midwifery, and consultative clinics and services should be available. Facilities for hospital treatment should be readily obtainable. The patient should not be discharged from the supervision of the doctor and midwife until four weeks after the confinement. This would to some extent reduce the difficulties which are met with in breast-feeding.

Voluntary and Municipal Hospitals

We owe a great debt of gratitude to voluntary organizations and hospitals in midwifery practice. I am glad that Mr. Ernest Brown—the Minister of Health—intends to retain these institutions in a general scheme for medical services. Voluntary contributions will be difficult to obtain after the war, and financial assistance will have to be given by the State if the voluntary hospitals are to retain their individuality. This may mean a loss of administrative control and independence, but the hospitals will gain by being included in the general scheme and given a definite position therein.

This will do away with overlapping and waste of beds in some areas, and will supply accommodation in other areas where hospital resources are inadequate. This would also reduce the long waiting lists for admission and the overcrowded out-patient departments. The voluntary hospitals have done much for teaching by supplying clinical facilities for the medical schools. The healthy spirit of competition does a great deal to make the individual wish to excel. Each special department of the large hospital is sponsored by an honorary head or "chief," who feels himself responsible for its efficiency and, by having a say in the appointment and control of his staff, expects whole-hearted co-operation and loyalty.

---

* Abstract of opening remarks in a discussion at the Obstetrical Section of the Royal Society of Medicine, May 15, 1942.

Consultants are now paid in hospitals such as those of the London County Council, some being whole-time and others part-time. The question is, Will the future generation of consultants be willing or able to serve as honorary members of the voluntary hospital staff? The answer is not far to seek. The traditions of the voluntary hospitals must not be lost, as they are a bulwark against a completely socialistic scheme of State service. Co-ordination of the hospitals is being achieved to some extent by the establishment of the Emergency Medical Service hospitals and by the Nuffield Provincial Hospitals Trust. These are on the lines of central councils and hospitals, with regionalization of areas. The Council of the King Edward's Hospital Fund for London has done much to improve the buildings and equipment of the voluntary hospitals. Would a whole-time State Medical Service give the same incentive to original research as the voluntary system? Would promotion depend upon clinical or administrative ability?

Participation of the G.P.

In general practice, midwifery has declined to a great extent owing to the efficiency of the midwives services, the establishment of clinics and hospital beds, and also because of the unsuitability of patients' homes. The decline of the birth rate is also a factor.

The national health insurance does not directly include the treatment of midwifery patients, nor does it give special consultant services and hospital accommodation. The panel doctor is too busy to take up midwifery practice with its inadequate remuneration, and he objects to the risk of criticism from local health authorities if cases should go wrong. Cottage hospitals have a limited number of local practitioners in attendance, and others may be excluded from the treatment of their patients when admitted. Small maternity homes should be established where the family doctor can admit and be responsible for the treatment of his own patients. Consultants and auxiliary services should be available from a larger supervising hospital centre.

In rural areas the family doctor would act in a part-time capacity, as he would have to undertake other branches of medical practice. Women prefer local hospitals, where they can be kept in touch with their families and relatives. The family doctor has been the trusted adviser and confidant of his patients as is the priest and lawyer. He is chosen because of the personal element. He knows the home conditions and circumstances as no whole-time practitioner or consultant can know. In official centres case records are open to the inspection of a staff which is under no Hippocratic oath. Consultation clinics do much to relieve the anxieties of the general practitioner, and discussions can take place as to diagnosis and treatment. The family doctor is, moreover, the first line of defence in the case of disease. But the doctor must have adequate training and must keep up to date by regular refresher courses in larger centres.

A team of doctors and midwives working in collaboration with a keen medical officer of health would ensure good results in these areas. Local clinics or centres could be established for interviewing and treating patients, but such centres would have to be instituted by the local health authority, as otherwise there would be difficulties of administration. Payment for work done would be given by the health authority and collected, when possible, from those patients who could afford to pay or who are specially insured. If any criticism arises it should be considered first by the committee of local practitioners and consultants before being judged by a lay board of management.

In Scotland, domiciliary midwifery is more in the hands of the general practitioners than it is in England and Wales. The midwives work directly under the doctor. The Scottish Board of Health Act, 1937, was a scheme for this co-ordination of practitioners, midwives, and consultants, and it has been established in a large number of areas. Lanarkshire, with its central maternity hospital at Bellshill, is a notable example of its efficiency. The patient has a choice of doctor from the local team of practitioners. The consultants on the staff of Bellshill Hospital must hold the membership or fellowship of the Royal College of Obstetricians and Gynaecologists.

A Basis for Discussions

The Russian public health services seem to provide a basis for many discussions on proposals for a State Medical Service in this country. In Russia all medical education is free and all doctors are whole-time practitioners under the U.S.S.R. The whole aim of the service is the prevention of disease. Every citizen has a right to free medical treatment. Some of the expense is recovered by contributory schemes of health insurance. Women in employment get full pay before and after confinement if off work. The medical practitioners get study-leave and retire on pensions. In the local areas are health centres or polyclinics, and these are linked up with larger centres and hospitals. The teaching schools and research department form the centre of the scheme. Local and central committees or soviets control administration.

A maternity service should give the patient a choice of doctor at the periphery, and consulting and specialist services should work towards the centre. There should be a central advisory committee composed of representatives from the universities, the Royal College of Obstetricians and Gynaecologists, the British Medical Association, Central Midwives Board, College of Midwives, hospitals, and other organizations interested in the practice of midwifery. The administration of such a maternity service should be in the hands of those who have a considerable knowledge of the practical side of obstetrics as well as of public health.

HYPEROSTOSIS FRONTALIS INTERNA*

BY

C. T. ANDREWS, M.D., M.R.C.P.

Physician to the Royal Cornwall Infirmary

Irregular formations of bone on the internal table of the skull have often been observed at post-mortem examinations and among museum specimens, but little notice was taken of the condition until Stewart in this country and Morel in France drew attention to the presence in these cases during life of symptoms suggestive of hypothalamic disturbances.

Cases in the Literature

Stewart (1927–8) recorded 5 fatal cases personally observed by him and called attention to their association with mental symptoms and obesity; and Morel (1930), describing the first living case, noted the presence of cataleptic seizures, excessive eating and drinking, adiposity, and delusions and hallucinations. There followed various surveys of radiological and museum material with a view to determining the frequency of the syndrome, notably by Sherwood Moore (1935, 1936a, 1936b), who carried out a survey of 6,650 radiographs accumulated over a period of 24 years; by Eldridge and Holm (1940), who described the x-ray findings in 200 patients consecutively admitted to a mental hospital; by Greig (1928), who examined 188 crania in the museum of the Royal College of Surgeons of Edinburgh; and by Yolton (1927–31), who described 4 specimens. The histories of many of these cases were reviewed, and in the last 12 years numerous additional cases have been published, notably by Van Bogaert (1930), Schiff and Trelles (1932), Eisen (1936), Moniz (1938), Hemphill and Stengel (1940), Gollan (1939), Casati (1936), Fracassi and Marelli (1936), Fattovich (1938), Roger (1938), Perkins and Biglan (1938), James (1936), Lehoczky and Orbán (1938), and Reider (1938–9).

Bartelheimer (1939a, 1939b) specially noted the association with diabetes. The literature on the subject is now fairly extensive, and it is interesting to note in this connexion that only 3 living cases were recorded before 1935—those of Morel (1930), Van Bogaert (1930), and Schiff and Trelles (1932). In view of the large amount of museum material it would seem that many examples of the syndrome were missed prior to that date. This argument, however, is hardly conclusive, for the surveys of radiological and museum material have shown that hyperostoses may be present without any symptoms, the patient dying from some unrelated disease. It seems clear from published observations that the hyperostoses are often present for a long time before any further symptoms develop. Bartelheimer, for example, noted that a patient of his had a chronic headache for 30 years before further symptoms appeared. About 50 cases in which definite hypothalamic symptoms were present, such as disordered fat metabolism, raised glucose tolerance, polyuria and polydipsia, and sleep disorders, have been recorded during life. In addition many of the patients have developed a progressive dementia, and in a few cases cranial nerve palsies have been noted, probably due to encroachment of new bone on foramina.

---

* Synonyms: Morgagni's syndrome (Henschen, 1936); syndrome of Stewart-Morel (Schiff and Trelles, 1932); metabolic craniopathy (Moore); intracranial osteophytes (Greig, 1928).

The marked preponderance in the female sex noted by Moore, Canavan (1938), Greig (1928), Dressler (1927), Carr (1936), and others serves to differentiate this condition sharply from a localized form of leontiasis ossea and from osteitis deformans, to which the bony changes bear a close resemblance in some cases. Some writers have, in fact, described cases under these heads—e.g., Schuller (1918), Bonnamour and Jamin (Morel, 1930). Another notable feature is the age incidence. The great majority occur about the menopause. Some, however, have been found among senile inmates of mental hospitals.

Radiological examination usually shows the hyperostosis as an irregular thickening of the vertical part of the frontal bone, the region of attachment of the falx being free. The surface may be irregular, with numerous spikes, or smooth and nodular. The outer table is never involved. In a few cases calcified masses have been seen in the sella turcica.

Careful microscopical examination of the hypothalamic region and pituitary has been made in only a few cases. Degenerative changes have been described by Morel, Stewart, and others, but in some cases nothing abnormal has been detected. It would seem, however, that the close association in function of hypothalamus with pituitary has not been realized by all observers, and in some instances failure to make a detailed examination of the pituitary may account for negative findings.

Case Record

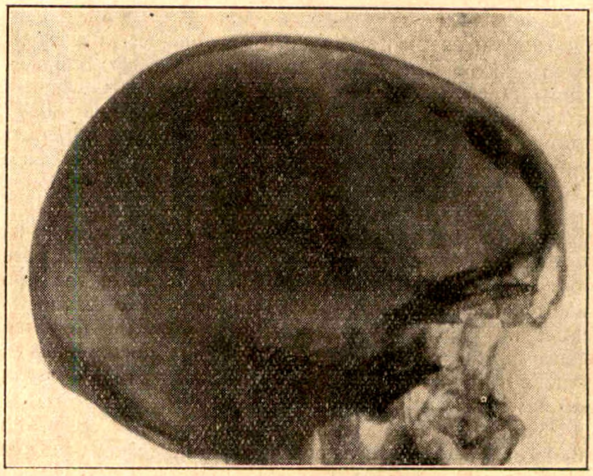
The patient, a female wardrobe dealer aged 45, had married twice and had had 10 living children. She had had one miscarriage—triplets when five months pregnant, in 1935. She had white-leg after this, and was of the opinion that all her trouble started then, as she had never felt well since. She began to have menorrhagia, with periods lasting eight days and intervals of two weeks. Hysterectomy—probably for fibroids—was performed in 1936 when three months pregnant. Between Aug., 1937, and Aug., 1940, she was four times in hospital with phlebitis of the left leg. In Aug., 1940, while in hospital, she was found to have glycosuria; a diagnosis of diabetes was made after blood-sugar estimations, and she was discharged on a 7-line diet and 40 units of insulin a day. Towards the end of 1939 she began to have narcoleptic attacks, which led to a cessation of insulin treatment, as they were thought to be hypoglycaemic. Later, however, insulin treatment was resumed, and subsequent attacks were considered to be due to diabetic coma.

The patient was evacuated to Cornwall in Oct., 1940, and was admitted to the Royal Cornwall Infirmary for suspected hypoglycaemic coma on March 14, 1941. She recovered consciousness shortly after arrival in hospital, but had several attacks in the next few weeks. Her weight had always been constant until the middle of 1940, when she suddenly began to gain. As this time coincided approximately with the beginning of the period of strict rationing, the gain in weight was considered odd. She was 11 st. 10 lb. on admission, having put on 2 st. in 9 months. There was no complaint of failing vision, but she noticed that before her sleepy attacks she went rather deaf. Her most troublesome symptom, apart from the attacks of somnolence, was a dull frontal headache which nothing seemed to relieve. There was no thirst, appetite was moderate, and the amount of urine was not increased.

Examination showed her to be of average mental development, with good memory and normal concentration; she was talkative and sociable, always ready to discuss her large family, with each of whom she kept up a correspondence. Pupils reacted sluggishly to light, more briskly on accommodation. Both optic disks were pale, especially in the temporal halves, and both visual fields showed concentric contraction. Moderate nerve deafness was present on both sides. There was general muscular weakness, particularly in the arms. The arm reflexes were normal; knee- and ankle-jerks were present; the plantar reflexes were flexor; and the gait was steady. No rhombergism and no incoordination to finger–nose or heel–knee tests were observed. There was a remarkable dulling of pain sensation on both sides over the trunk and all four limbs: so definite was this that a needle could be introduced anywhere without complaint of pain. Stereognosis was normal. Tactile localization and discrimination, compass points, and joint sense were also normal. The heart was slightly enlarged, and the blood pressure 160/80. The liver was palpable an inch below the costal margin. There were noticeable fat deposits on the buttocks, thighs, and lower abdomen, but no nodules and no tenderness.

Narcoleptic Attacks.—These came on at irregular intervals. Sometimes there would be several in a day, sometimes freedom for a week. They lasted from a few minutes to an hour, and occurred at any time of the day. None was observed during the night. They started with a dull headache that lasted for several hours, after which she passed into a sleepy state and could be roused with difficulty. The pupils were normal in size, but no reaction to light could be obtained during the attack. The limbs were spastic, with exaggerated deep reflexes, but the plantar reflexes remained flexor. Ankle clonus was observed on both sides on one occasion. During the attacks she perspired profusely, and on being roused complained of feeling cold. Pain sensation, visual fields, and hearing, tested roughly during the period of recovery, showed further restriction. Onset and termination were never abrupt. Once she had visual hallucinations when recovering from an attack. The blood sugar during one attack amounted to 130 mg. per 100 c.cm.

Glucose tolerance estimated in a clear interval showed: fasting blood sugar, 150 mg. per 100 c.cm.; one hour after, 210 mg.; two and a half hours after, 190 mg. The blood urea was 29 mg. and the serum calcium 9.8 mg. per 100 c.cm. The cerebrospinal fluid was clear, and showed no increase in pressure: cells 2 per c.mm.; albumin 0.025%; globulin normal; chlorides 750 mg. per 100 c.cm.; sugar 0.08%. Urine examination revealed glycosuria on an average of three days out of four. Specific gravity averaged 1026. There was nothing abnormal on microscopical examination. The temperature chart showed several unaccountable rises to 99.4°, but was otherwise normal. Radiologically, no changes were present in any bones other than those of the skull, a radiograph of which is here reproduced.



Hyperostosis on the internal surface of the frontal bone. Diploe is invaded at one point, but the outer table is not involved. Antero-posterior view, midline free; enlarged frontal sinuses.

During her time in hospital she had one troublesome attack of phlebitis in the left leg. The narcoleptic attacks were so well controlled by 10 mg. of benzedrine sulphate daily that in the three weeks previous to discharge she had only one attack of short duration.

Discussion

In view of the association of pituitary and other endocrine function, present interest centres largely on the possibility of the bony changes being due to some disorder of parathyroid secretion. While it can hardly be said that the secretion of a parathyrotrophic hormone by the pituitary has been proved, a number of observations are at least suggestive—e.g., the association of parathyroid adenomata with hypophysial tumours noted by Hadfield and Rogers (1932), Gerstel (1938), Husslein (1939); the degenerative changes in the parathyroids of hypophysectomized dogs noted by Koster (1928), Houssay and Sammartino (1933, 1934), and Smith (1927); and the effects of pituitary extracts in causing parathyroid enlargement, noted by Anselmino and others (1935). In an examination of the parathyroids reported by Hemphill and Stengel (1940) it was found that three of the four glands present were unusually small. The three smaller glands showed an increase of pale oxyphil cells; the fourth was formed exclusively of these. These changes suggest overactivity in a set of glands which for some reason were smaller than normal. Serum calcium changes have been noticed in only a few cases; in a series examined by Tager, Shelton, and Matzen (1939) the figures were within normal limits.

Further problems are those presented by the high incidence in the female sex (98% in Moore's series) and the restriction of bony changes to the frontal bone.

From the point of view of diagnosis the importance of the syndrome lies in the danger of treating the patient for something she has not got. My patient has been treated once as a case of hypoglycaemia and once as a case of diabetic coma. The fact that she was insulin-resistant probably saved her from harm on that occasion. In some cases, however, a diagnosis of cerebral tumour has led to unnecessary operation. A knowledge of the existence of the syndrome should serve to protect from these mistakes, and a radiograph of the skull which includes the frontal bone will always serve to establish the diagnosis.

Summary

A case of hyperostosis frontalis interna is described and the literature briefly reviewed. Features of the case were narcoleptic attacks controlled by benzedrine, increased glucose tolerance, sudden gain in weight, restricted fields of vision, nerve deafness, and typical radiological findings.

The importance of the syndrome lies in its differentiation from conditions requiring active medical or surgical intervention.

P. Robinson (*Amer. J. Dis. Child.*, 1941, **62**, 701) during the last two years has seen at Tel Aviv six cases of favism, an acute haemolytic anaemia due to ingestion of woad berries (*Vicia fava*) and hitherto unknown in Palestine. Favism is most common in Sicily and Sardinia, but only sporadic in other countries. The onset is sudden, with vomiting and diarrhoea, the skin turns pale grey, the eyes become sunken and consciousness clouded. The red cells sink to 1,000,000 or less per c.mm. and the haemoglobin content to 10%. Recovery, which begins spontaneously, is assisted by blood transfusion and takes place in from one to two weeks. Deaths are rare. Its course is like that of Lederer's anaemia, but in favism relapses are common.

ACUTE LARYNGITIS AND SEPTICAEMIA DUE TO H. INFLUENZAE (TYPE B)

BY

S. DE NAVASQUEZ, M.D.
Pathologist, E.M.S.; Department of Pathology, Guy's Hospital Medical School

Attention has recently been drawn by Sinclair (1941) to a very severe and often fatal form of acute laryngitis and septicaemia in young children due to *Haemophilus influenzae*. These infections have occurred with increasing frequency in the U.S.A., and the following case is the first of a similar nature to be recorded in this country.

Case History

A male child aged 2 was admitted on Dec. 15, 1941, for laryngeal stridor. He first became ill 2 days previously, when he began to scream, and it was noticed that his breathing was difficult. This persisted until admission.

On examination the temperature was 101° F., the pulse rate 156, and the respirations 28 a minute. The latter were accompanied by inspiratory stridor and recession of the intercostal spaces. The uvula and fauces were symmetrically swollen and very hyperaemic, but no membrane was visible. Laryngeal diphtheria was diagnosed, and 65,000 units of antidiphtheritic serum were given intramuscularly in 5 doses over 12 hours. The laryngeal obstruction was so severe that tracheotomy was done 3 hours after admission, and while this relieved the stridor and temporarily improved the pulse rate, the latter and the respiration rate soon returned to 160 and 32 respectively. The clinical condition remained poor, the child being prostrated. On the 18th a pleural rub appeared at the right base and he was put into an oxygen tent. The following day there were signs of bronchopneumonia, for which sulphanilamide was given. He died in coma on the 21st, 6 days after admission.

Bacteriological examination of a throat swab on admission gave a growth of *Corynebacterium hoffmanni*, which was confirmed on Horgan and Marshall's medium. Swabs taken from the larynx at the tracheotomy gave a pure growth of *H. influenzae*. Repeated swabs from the nose, throat, and larynx failed to grow *C. diphtheriae*. The blood count showed haemoglobin, 74% (Haldane); white cells, 9,600 per c.mm.

Necropsy

This was performed 22 hours after death, and revealed a well-developed, well-nourished male child with no external abnormality except a clean tracheotomy wound. The pericardial sac was distended with approximately 80 c.cm. of thick yellow purulent exudate, which was moderately adherent to both layers. The myocardium, endocardium, valves, coronary arteries, and great vessels were normal. The larynx, glottis, trachea, and main bronchi were normal except for a clean incision in the trachea. Both pleural cavities were filled with thick yellow pus extending into and encysted in the interlobar septa. The lungs were compressed but air-containing, and exuded a little frothy fluid on pressure. No pneumonic consolidation or bronchitis was detected. The mediastinal glands were slightly enlarged and congested, but were otherwise normal. The mouth, fauces, tonsils, pharynx, oesophagus, stomach, intestines, mesentery, and peritoneum were normal. The liver was enlarged and pale from fatty change. The gall-bladder, biliary passages, and pancreas were normal. The spleen showed lymphoid hyperplasia only. The genito-urinary, endocrine, and central nervous systems were normal.

Microscopical Examination.—Sections from the heart and lungs revealed severe purulent inflammation and numerous Gram-negative bacilli. The lung parenchyma showed a little albuminous fluid in the alveoli but no evidence of inflammatory disease. In the liver there was severe fatty change only.

Bacteriological Examination.—Cultures from the pleura, pericardium, and heart blood gave a pure growth of *H. influenzae*. The cultures grew well on boiled blood agar, and the colonies were smooth; suspensions in normal saline were agglutinated* by Type B serum to a titre of 1/100. No agglutination was observed with Types A, C, D, and F in any dilution.

Discussion

It is difficult to evaluate the pathogenicity of *H. influenzae* in man owing to many strains which appear to lead a saprophytic existence in the human nasopharynx; while others are capable of rapid invasion and often fatal infections typified by well-recognized entities such as meningitis and bacterial endocarditis. Its possible role in producing disease of the respiratory tract is less well defined, and in view of its normal habitat it is surprising that it is not more often encountered as the sole pathogenic agent. One of the difficulties may be due to failure to distinguish between pathogenic and non-pathogenic strains, and between primary and secondary invaders. Pittman (1931) has, however, demonstrated that pathogenic strains are usually capsulated and that the capsules have a specific soluble antigen which renders them capable of differentiation into 6 serological types (A to F). The majority of strains isolated from "influenzal" meningitis are Type B, and Sinclair has shown that the strains recovered from cases of laryngitis with septicaemia also belong to this type. The latter author collected 10 such cases, 8 of them in 18 months, and suggests that the number is increasing.

---

* These sera were made available through the kindness of Dr. Margaret Pittman of the U.S.A. Public Health Service, to whom I am greatly indebted.

The clinical picture of severe prostration and acute respiratory distress of abrupt onset, often necessitating tracheotomy, differs from that of laryngeal diphtheria in that the prostration is undiminished by tracheotomy or antidiphtheritic serum therapy. The disease may run a rapidly fatal course in from 18 hours up to 6 days. Four of Sinclair's 10 patients died, those who recovered having received sulphanilamide, sulphapyridine, or sulphathiazole.

The diagnosis is essentially a bacteriological one, depending on the isolation of *H. influenzae* by culture from the nasopharynx, larynx, lung, or blood, or by direct typing of nasopharyngeal mucus obtained by swabbing with type-specific serum—the Neufeld technique, used by Alexander, Craig, Shirley, and Ellis (1941). Since typing sera are not yet available in this country, diagnosis largely depends on isolation by culture; but uncertainty will arise unless serological typing confirms the strain—otherwise the diagnosis can only be presumptive.

The present case affords an opportunity of discussing the pathology. The organism was first isolated from the throat on the third day of the disease and from the larynx on the fourth, where it had probably been present from the onset of respiratory distress. Evidence of pulmonary disease was first detected on the fifth day, and necropsy proved it to be due to empyema, no inflammatory condition of the lung parenchyma having been found. Post-mortem blood culture was also positive, and judging from 7 of Sinclair's cases in which the organism was recovered from the blood ante mortem, the blood in the present case was probably invaded in the early stages, thus emphasizing the highly invasive property of this particular strain of *H. influenzae*—not unexpected in view of its possessing a capsule analogous to that of type-specific pneumococci. The route taken by the organism was probably the lung—a probability that is suggested by the bilateral empyemata and pericarditis, in which the exudate in both the pleurae and the pericardium was too abundant to have formed as a terminal event secondary to the septicaemia. The absence of any inflammatory disease of the upper respiratory tract at necropsy shows that the initial lesion may resolve and that the fatal outcome in those cases which survive the first few days is due to purulent inflammation of the lungs, pleurae, or pericardium, and septicaemia, or, when the former are absent, to septicaemia alone.

Summary and Conclusion

A case of acute laryngitis and septicaemia due to *H. influenzae* is described.

The strain of haemophilus isolated from the larynx and blood belongs to the well-recognized pathogenic Type B (Pittman).

The diagnosis depends on isolation of the organism from the nasopharynx and blood, employing a suitable medium such as boiled blood agar or by direct typing of nasopharyngeal mucus when typing sera are available.

The pathology of the condition is discussed briefly.

I am grateful to Mr. W. H. Clark, who was responsible for isolating the organism and for its typing.

ATYPICAL ASPHYXIAL DEATHS

BY

NORMAN PATTERSON, M.B., B.Ch., D.P.H.

Temporary Assistant Medical Officer, Central Hospital, Warwick

The remarks of Dr. Eric Gardner in his paper to the Medico-Legal Society described in the *Journal* of April 18, 1942 (p. 502), under "Mechanism of Certain Sudden Deaths," are timely not only from the point of view of correct inquest findings but also in instituting prompt skilful treatment if there is still a chance of life. Dr. Gardner's remarks have been read by the staff of this mental hospital with considerable interest and with a certain degree of relief. Within the past two months it has been my unfortunate lot to have lost three female patients through asphyxiation. The superintendent tells me that within his eleven years' experience here he cannot recall any deaths with similar surrounding clinical and post-mortem evidence.

Case Reports

Case 1.—A woman aged 36 fell on a tiled floor. She was rendered unconscious and was treated for a fractured skull. She regained consciousness within 4 hours, improving rapidly, and was left by the nurse in charge for a few minutes while she attended to duties in the day-room. On her return the patient was dead. It being thought that this sudden catastrophe was inconsistent with the intracranial injury, a necropsy was performed, revealing that the pharynx contained a huge mass of bread impacted above the epiglottis. The bronchial tubes and lungs also contained pieces of inhaled bread. The base of the skull was fractured, but without sufficient trauma or haemorrhage to cause sudden death. The bread could have been given to the patient only by some of her well-meaning friends.

Case 2.—A woman aged 44. This patient, at the breakfast table, devoured her own share of bread-and-butter and, while standing up and about to snatch that of her neighbour, was seen by the nursing staff to slump down into her seat and collapse. Attempts to recover foreign matter from the mouth were unsuccessful, and she died within 5 minutes. The necropsy revealed bread tightly packed in the pharynx, trachea, and bronchi.

Case 3.—A woman aged 65 was noticed by the nursing staff to turn pale and collapse in her seat while eating bread at the breakfast table. Her air-passages were cleared so far as was possible, but she died within 7 minutes. The post-mortem examination revealed soft bread scattered throughout the larynx, trachea, and bronchial tree.

Commentary

The victims were female patients of a mental hospital, and in Cases 2 and 3 were known to be food-snatchers who, not being content with their own ration of bread, would grab at their neighbours' and cram it into the mouth without mastication. The usual signs of choking were absent in the two observed cases: no lividity, cyanosis, coughing, struggling for breath, or convulsive movements.

A feature common to all three cases was a pallid, peaceful facies. The external post-mortem signs of asphyxiation, such as livid patches on the body and extremities, were absent.

The absence of the normal reflexes, through the medulla, of coughing or retching is remarkable in the light of the pathological findings of impaction in the region of the most sensitive receptors for producing them—viz., the larynx, bronchi, and trachea. Considered with the time factor of 5 and 7 minutes in the two observed cases, it is clear that the mode of death could not have been true asphyxia.

Death appears to have been due to syncope set up by shock—the result of a mass reflex through the impaction of foreign matter in the pharynx, larynx, trachea, and bronchial tree, death taking place before the usual signs and symptoms of asphyxiation had become manifest.

I am indebted to Dr. D. N. Parfitt, medical superintendent, for permission to record these cases, to Dr J. L. Berry for the post-mortem examinations, and to both for their encouragement in my presentation of this paper.

Medical Memoranda

Treatment of Poliomyelitis with Convalescent Serum and Sulphapyridine

The following two cases of poliomyelitis in the same family are an interesting contrast. In Case 2 the diagnosis could be made with certainty although there was no paralysis, and treatment with convalescent serum and sulphapyridine was given within 48 hours of the onset.

Case Reports

Case 1.—M. W., the youngest of a family of 4 children, was taken ill on Oct. 4, 1941, and was admitted to hospital on Oct. 8, when he presented the following signs: Temperature 101.2°, pulse rate 126; he was conscious and intelligent, but drowsy; his pupils were dilated; there was marked neck rigidity; Kernig's sign was positive; abdominal reflexes and knee-jerks were absent. Lumbar puncture gave a clear colourless fluid, which showed: protein, 0.23% ; globulin, *nil* ; sugar, greatly diminished, not sufficient to estimate; chlorides, not sufficient to estimate; cells, nearly all lymphocytes, 134 per c.mm. On Oct. 9, 5 days after the onset of symptoms, he developed flaccid paralysis of both arms and legs and became slightly cyanosed, respiration being mainly diaphragmatic. By Oct. 13 paralysis of his respiratory muscles was so extensive that it became necessary to nurse him in a Booth respirator. In this he remained until Oct. 17, when his intercostal muscles had sufficiently recovered to allow of his removal. Since then there has been some improvement, and at the end of April, 1942, his general health was excellent. He had almost complete paralysis of the muscles of his back, left arm, and right leg, some useful movement of his right arm and left leg, and almost complete recovery in his intercostal muscles. There could be no doubt as to the nature and severity of this illness.

Case 2.—P. W., aged 13, brother of Case 1, complained of pain in his back and headache on Oct. 10 (a week after the onset of his brother's illness). He was admitted to hospital on Oct. 11. On admission his temperature was 102°, pulse 130, and respirations 30. His fauces, heart, and lungs were normal. There was slight neck rigidity, and Kernig's sign was positive. There was no paresis, and the deep reflexes were present. His abdominal reflexes were absent on the right side. Lumbar puncture yielded a few cubic centimetres of fluid which was not under pressure and on which the pathologist's report was as follows: "Fluid slightly turbid, with large blood-stained clot. Protein, 0.30% ; sugar diminished; Nonne-Apelt reaction, globulin +; chlorides, 0.75% ; cells, 456 per c.mm., mixed polymorphs and lymphocytes (some cells accounted for by blood); culture, sterile."

The treatment adopted was as follows: In the first 24 hours after admission he received 7.5 g. of sulphapyridine, the first dose being given (intramuscularly) at 6.30 p.m. on Oct. 11. Subsequent doses were given by mouth. The dose in the second period of 24 hours was 6 g., and in the third period 3 g., a total of 16.5 g. On Oct. 12 convalescent serum was available and 20 c.cm. was given intramuscularly at 10.45 a.m. This dose was repeated at 6.45 p.m., and again morning and evening on the 13th, and once on the 14th—a total of 100 c.cm. in five doses. The boy developed no further symptoms. His temperature fell to normal on Oct. 14 and showed no subsequent rise. There was no alteration in his physical signs except that on Oct. 13 the abdominal reflexes were absent on both sides. They were not obtained until Oct. 17. He was discharged on Nov. 9 and has remained in good health since.

Comment

The fact that no paralysis developed in Case 2 would appear to justify a more extended trial of convalescent serum and sulphapyridine, particularly in cases like this in which the diagnosis can be made with certainty before the onset of any paralysis. It is fully realized that the fact that no paralysis developed in the second case may have been a coincidence.

I am indebted to Dr. L. B. Cole for his help in the diagnosis of Case 1 and his suggestion that the combined treatment should be used if further cases occurred; and to Dr. Sinclair Miller for very promptly supplying 100 c.cm. of convalescent serum with instructions as to dosage.

Bernard E. A. Batt, M.B., B.Ch.

West Suffolk Hospital, Bury St. Edmunds.

Reviews

POSTGRADUATE LECTURES

Edinburgh Postgraduate Lectures in Medicine. Volume II. 1940-1. (Pp. 540. 12s. 6d.) Edinburgh and London: Published for the Honyman Gillespie Trust by Oliver and Boyd. 1942

The Honyman Gillespie Trust is to be congratulated on producing a second volume of postgraduate lectures in these difficult times. Physical examination should begin with inspection, unwilling though the student is to realize that fact, so Mr. F. E. Jardine's lecture on the subject is appropriate. Since it is mainly surgical in outlook we would commend the executive committee to secure an equally interesting contribution from the medical side, for the patient who has the disease is as important as the disease he has. Just as medical examination should begin with inspection so medical theory must be largely rooted in genetics. Prof. Crew's lecture on genetics in relation to reconstructive medicine is therefore of particular value, coming from an authority in genetics who has, however, no exaggerated ideas on the advantages of artificially controlled propagation, since, as he says, most derangements and defects of genetic origin behave as recessives. He anticipates more results from improving the environment, though aware that improvements in social conditions will not in themselves yield unlimited evolutionary progress. The whole lecture repays thoughtful study. Of topical interest is Prof. D. K. Henderson's lecture on the significance of fear, which links up with Prof. F. R. Fraser's study of the so-called effort syndrome. This he regards as a disorder of the involuntary nervous system which also occurs in civil life but is given almost specific characters under conditions of war. Since 1914 the mental features have been realized and accepted, so that we may now anticipate better results from more discerning treatment. Prof. Stanley Davidson contributes a helpful article on recent developments of diagnostic sternal puncture, while Dr. C. P. Stewart takes a cautious view of the relationship between dark adaptation and vitamin A, holding that other factors such as age, fatigue, minor infections, and indeed other vitamins also play a part. The recent increase in pulmonary tuberculosis lends point to Dr. Charles Cameron's account of modern methods in its treatment. He does not believe the failure in early diagnosis is so often due to carelessness or ignorance as is often suggested, but rather to the fact that some cases are symptomless in the early stages, while others are so acute in onset that much damage is wrought in a comparatively short time. Nature at the best holds a fine balance, and he quotes the depressing dictum that "60% of all adult pulmonary cases die within five years of coming to our notice." Clearly more active measures are called for.

Naturally a considerable proportion of the lectures deal with medical and surgical problems arising from the war, to which we have devoted a considerable amount of space in these columns. An attractive series is brought to a conclusion by a suggestive if rather discursive paper by Prof. McDowall on the physiological approach to medical problems.

EVOLUTION OF SURGICAL INSTRUMENTS

The History and Evolution of Surgical Instruments. By C. J. S. Thompson (Pp. 113. No price given.) New York: Schuman's, Twenty East Seventieth Street.

Now that so many of the original instruments with which this book deals have been destroyed by enemy bombing, it is as well that a concise account of them should be available in a single volume such as this, even though a good deal of the matter of the book has already appeared as articles in the *British Journal of Surgery*. As Dr. Chauncey D. Leake, who introduces it, tells us, this historical survey can never supplant the instruments themselves, but it may serve to perpetuate the purpose of the collection. It forms an interesting addition to the instrument catalogue of the Museum of the Royal College of Surgeons of England, copies of which fortunately still exist. The book, which is amply illustrated and beautifully produced consists of twelve chapters, of which "The Scalpel," "The Trepan," "Head Saws," and "Tourniquets" may be selected as samples. Possibly those on "Tourniquets" and "Trocars," respectively, are two of the most interesting. It is regrettable that there are many omissions and some inaccuracies. Sir Victor Horsley at one stage of his career may have used the Walsham trephine depicted on p. 44, but he designed and used the well-known truncated cone type of instrument, still used on occasions to-day, which is not shown in this book and might well have been included. Ambroise Paré's "skull compass" is the prototype of Souttar's and Trumble's craniotomes which are not, however, mentioned, and which, if illustrated, would form with it an interesting comparison of more recent instruments. There is no reference to the power-driven skull saws of Doyen and Van Arsdale, and it is quite inaccurate to describe, in the chapter on the trepan, Lambert Rogers's modern electrically driven craniotome—the skull plough—as a reversion to primitive times. Any reference to this instrument, which has no counterpart among trepans, should be in the chapter on head saws, since it is in essence an electrically driven bone saw capable of controlled movement in two planes. The very widely used Gigli wire saw is not mentioned, nor is there any reference to what so far as we know is the only really complete account of this subject of skull saws, viz., "The history of craniotomy, an account of the methods which have been practised and the instruments used for opening the human skull during life" (*Annals of Medical History* (1930), p. 495).

A bibliography is not included, references are conspicuously few (the important monograph of J. S. Milne on *Surgical Instruments in Greek and Roman Times* is not mentioned), and mistakes of printing occur in both text and index. Murrett-Baker (pp. 68 and 70), is surely Morrant Baker, and Roger (p. 112), Rogers. A final chapter on operating tables concludes with illustrations of a British table of 1885 and a French one of 1914. Although, so far as it goes, this is an interesting account, we cannot but regard it as somewhat superficial, and would welcome a further elaborated edition in which references and bibliography are included and attention is paid to some of the points here raised.

HISTOLOGY AND EMBRYOLOGY

Histology and Embryology. By José F Nonidez, Sc D. Oxford Medical Outline Series. (Pp 199 12s. 6d.) London: Oxford University Press

This book, by Prof. Nonidez, is described by the author as an "outline which presents in condensed form the most important facts concerning the structure and development of the organs of the human body," and as "intended to be used as a supplement to a textbook." Like other books of a similar nature, this work appears to have been written with the purpose of supplying the want which is felt by many students of a reliable guide to the essentials of a subject which will save them both time and expense. There is, however, a very real danger that such books may supplant rather than supplement well-illustrated standard works which have been gradually perfected during many successive years. Elementary books without illustrations, and consisting of verbal descriptions only, leave a great deal to the imagination of the reader, who—especially in subjects like histology and embryology—requires clear-cut and accurate illustrations to assist him in interpreting the appearances he sees under the microscope. The work which we are now considering is clearly written, information being imparted by short definitions which are admirable from a didactic standpoint. One would like, however, to have seen greater attention paid to the relations of structure to function, and also greater detail given to the description of the development of those parts which have a practical bearing on medical work—e.g., in connexion with the occurrence of abortion, chorion epithelioma, hare-lip and cleft palate, hypospadias or spina bifida, and in general the effects of malnutrition or disease on the early stages of a normally developing embryo. The student who studies the structure of the skin or other part with the view of understanding the relation of this to its normal functions, and has a good mental picture of that structure, will be quite independent of didactic aids to his memory, and more especially so if his attention has been directed to the bearing that this has upon ordinary medical practice.

ABNORMALITIES IN BACKWARD CHILDREN

Developmental Aphasia in Educationally Retarded Children By M. MacMeeken, M A., Ph D (Pp 95. 3s) University of London Press, Ltd., St. Hugh's School, Bickley, Kent.

It is a matter of common observation that retardation of learning in school is by no means always associated with general mental deficiency—i.e., with general lack of capacity for intelligent development. The existence of congenital word blindness due to lack of development of certain specified areas of the brain as suggested by Hollinshed has been hotly disputed, but that specific reading and spelling disabilities are not uncommonly met with among elementary school children is the experience of every teacher. Dr. MacMeeken has investigated 140 children on the "retarded list," 84 boys and 56 girls from a background of 1,487 children. He found that a large proportion of these owed their retardation to factors other than low capacity, and that this is especially true of boys. He found that 58.6% of this group were "left eyed" and that the proportion of boys was again high. Squint and left-handedness also seemed to be significantly associated with retardation, and a previous investigation showed that these were associated with an aphasic confusional error.

The determining cause of laterality is little understood, but abnormality of foetal posture has been suggested, and left laterality does seem to be associated with twinning. The point is that studies of induced nystagmus show that left-eyedness means a preference for scanning from right to left, whereas written language requires a scanning from left to right—an obvious cause of aphasic confusion which may well induce a retardation of reading and spelling.

This well-documented essay will be of great value to all who are interested in the relation of developmental abnormalities to intellectual and learning capacity, a subject which concerns the medical as much as it does the teaching profession.

Notes on Books

The official *Medical Register* for 1942 has been published on behalf of the General Medical Council by Constable and Co. (Orange Street, W.C.2) at 21s., post free 22s. The table printed in the introductory section shows that 3,293 names were added last year. New registrations numbered 1,189 in England, 632 in Scotland, 285 in Ireland, 134 on the colonial register, and 1,053 on the foreign register. The total number of names on the *Register* at the end of last year was 66,995, being 2,316 more than on December 31, 1940. The number of names removed from the *Register* during 1941 was 993; of these 985 were deleted on evidence of death, and 8 were struck off under the disciplinary powers conferred by Parliament on the General Medical Council.

Prof. JOHN READ of the University of St. Andrews has written an entertaining little book for popular reading on *Explosives* (Harmondsworth, Penguin Books Ltd., 9d.). He describes the chemical nature of explosive phenomena, the various uses which different explosives serve, the method of their production, and gives some account of the quantities in use. It is full of information relating to their specific characters, which vary greatly in sensitivity to shock and other conditions, and describes how each of the different characters is turned to advantageous use. It is interesting to observe some unexpected methods of producing explosives for application to special purposes, such as a mixture of liquid oxygen with finely powdered carbon or carbonaceous matter, and to note that practical use is made of liquid carbon dioxide alone, inert though it is, as an explosive.

Modern Treatment in General Practice Yearbook, 1942, is the eighth annual volume of papers on therapeutics reprinted from the *Medical Press and Circular*. It is published at 12s. 6d. from the office of Baillière, Tindall and Cox, and the editor, Surgeon Rear-Admiral CECIL P. G. WAKELEY, contributes a brief preface. A wide range of subjects is covered; and there are fourteen articles grouped together under the general heading "War Medicine and Surgery."

A seventeenth edition of *Black's Medical Dictionary*, which was edited for many years by the late Dr. J. D. COMRIE, has been published by A. and C. Black at 21s. The main text consists of over 1,000 pages printed in double columns, and there is a brief supplement on the management and treatment of casualties resulting from air raids.

THE MEDICAL CURRICULUM

The final examinations are over. The successful candidates have a brief six months to adapt themselves to a world whose ideals and demands will prove very different from those of the medical schools in which they were trained. It will not be long before director-generals, scientific advisers, and politicians begin to pass adverse comment on their want of *savoir faire*, their ignorance of nutrition, and their lack of insight into the problems of industrial welfare. The bizarre group of patients with physical signs, who have been with such difficulty collected for the great occasion, have returned to the infirmaries and sanatoria which permanently house them or passed on to that bourne from which no traveller returns. The hospitals breathe a sigh of relief and get on with the treatment of their normal clientele, which, rather surprisingly, seems to be in large measure unsuited to the purposes of a final clinical examination. But no such respite is allowed to the examiners, who must now busy themselves with the revision of the medical curriculum, a problem to which many of them have devoted unrewarded hours in the past. The recrudescence of interest in medical education is in part due to a general stimulation by the ultra-violet light of war; in part to the anxiety felt by the universities about the deterioration threatened by the dispersion of medical schools and the loss of teachers, especially in clinical subjects; and in part, and perhaps most urgently, to the knowledge that an Interdepartmental Committee on Medical Schools is now in action. As this committee is to inquire into the organization of medical schools, with particular reference to facilities for clinical teaching and research, the result of present discussions is likely to be concrete and far-reaching. A little probing at the roots of the matter may therefore not be out of season.

At least three important committees considered the medical curriculum in the decade before this war, and their issue was stillborn. They did not succeed in adapting the curriculum to the inflow of new knowledge or in shifting the emphasis from the study of disease to the prevention of illness. It is important to inquire why this was so. Let it be said quite bluntly, for we are sadder and wiser now than we were then, that we did not apply science, or at any rate the appropriate science, to our task. The committees of the General Medical Council and of the Combined Universities were entirely composed of medical teachers. The committee of the British Medical Association contained general practitioners, and conferred with the teaching profession. Methods of teaching of students and selection of teachers in the medical schools still have the features of a primitive craft which has grown up in a haphazard way and which calls for scientific analysis and re-integration. Education is a science which has a theory, a discipline, and great recent advances. No one with eyes to see can fail to be impressed by the help which educationists and psychologists have given to our rapidly expanding Defence Services in schemes of pre-selection and training. The speed of acquisition of industrial skill as a result of methods introduced during the war has been no less remarkable. No revision of the medical curriculum can afford to neglect this revolution or fail to ask expert help from outside. To do so would be to run counter to one of the main principles for which we ourselves stand as a profession of technical experts. *Experto crede.*

Next we must decide what is the principal aim of medical education. Surely it is the production of good general practitioners. The exceptional man who is likely to become a consultant or researcher can—up to a point—look after himself, and in any event he should not bias the curriculum. Not long ago, in reviewing Alan Gregg's *Furtherance of Medical Research,* we commented on the widening gulf between medical research and medical practice. The staff of the Medical Research Council's institute is now predominantly non-medical. The recent appointment of a distinguished non-medical biochemist, Prof. C. R. Harington, as its head, won universal approval. Medical education cannot legislate for the researcher as well as the general practitioner; it must fit its courses for the latter. It seems, therefore, that we must work back from the medical practitioner: we must find out what knowledge and bodily skills he requires. This information can only be obtained by field surveys, carried out by groups including medical and non-medical workers, to discover what the practitioner is now doing and what he ought to be doing. These surveys will be coloured by the knowledge that the future practitioner will almost certainly have to undergo a period of compulsory house appointments before registration of his qualification, and a period as assistant at a health centre or in a practice before he is allowed to work entirely on his own.

When the information about the appropriate mental and technical equipment of the practitioner of to-day and to-morrow has been collected the educationists must help us in devising the best way of teaching it. The scholastic life of the medical student falls into three divisions—school education, pre-clinical education, clinical education—and between the first and second there may perhaps be interposed a period of national service. It will again pay us to work backwards. Our plans must bear in mind that the cost of the student's education will be borne to an increasing degree by the State and must bear a reasonable ratio to the service provided afterwards. It is undesirable that young men and women should remain *in statu pupillari* after the age of 23 or 24 unless we are deliberately aiming at breeding out our best stocks. Many of them are marrying at that age to-day.

Clinical education might be carried out in three distinct ways: the old-fashioned apprentice training of "walking the hospitals," which has continued with little change up till to-day; the fundamental scientific or physiological approach for which many teachers hanker; and the synthetic type of training which has proved so valuable in the Services and which depends on discovering what the pupil has to learn and then working out the most efficient way of teaching it. It seems *a priori* unlikely that it will be found that the present routine of medical and surgical ward clerkships, or the present teaching by men who are chosen for their professional skill, and who have a duty to get round the ward, to perform their operations, or to examine their out-patients, is the best that can be devised or afforded. It is also clear that life is too short for the medical student to learn everything from the fundamental or scientific standpoint, and it seems probable that he will have to get his scientific education and background in his pre-clinical years and devote the clinical years to the acquisition of technical skills. We must probably look forward to a much greater extension, under whole-time teachers, of what are now known as preliminary medicine and surgery, and a much more intimate fusion of clinical teaching, pharmacology, pathology, and radiology. There is need here for a survey of more modern teaching methods, such as the combined demonstrations of clinical, pathological, and radiological material which have been prepared at some of the Scottish universities or the lay-out of our new museums. Training Command of the R.A.F. is almost too gadget-minded and not always appreciative of the difficulty of transference of skill from the artificial to the real, but it has shown what can be done with the film, the sound-track, and the model or "mock-up," and suggests possibilities in medical education. Developments of this kind will greatly affect the physical structure and cost of medical schools and the type and training of teachers, and are very germane to the evidence to be presented to the Interdepartmental Committee.

School education and the pre-clinical education of the medical student must be planned in association with the general education of the young people of Britain and not as an isolated medical problem. Here, too, we are in danger of getting out of touch with the extensive study of general educational problems which the war has stimulated. As regards pre-clinical training, it is not clear why the anatomy and physiology of the body should leave so little time for the study of the mind. The reasons must lie in the historical development of the medical schools and not in a true appreciation of the needs and possibilities of medical education to-day. The pre-clinical years are likely to become the backbone of the doctor's education as a scientist, and no time or care should be spared in their planning.

New efforts to reform the curriculum will be as abortive as the old if planners think in terms of the claims of rival teachers, the clash of personalities, and peace by compromise. Neither in the pre-clinical nor in the clinical course can we keep the curriculum up to date and of reasonable length by the processes of addition and subtraction. We require new permutations and combinations. The present century has seen revolutionary changes in methods of diagnosis and treatment, in understanding of the psychological causes of illness, and in the prevention of organic and functional disease; and only fundamental changes in the curriculum and the methods and scope of medical teaching can keep pace with them.

FOUR YEARS OF HERBERT'S ACT

In piloting through Parliament so radical a reform of the divorce law as the Matrimonial Causes Act, 1937, Mr. A. P. Herbert achieved a very remarkable success. He succeeded largely by concentrating on a few basic principles and not inviting controversy over many minor details, desirable though these might have appeared. The Act has now been administered for about four years, and few will maintain that it has not on balance been very beneficial. That it should have shown a good many rough edges is inevitable, for under the conditions of its passage through Parliament the persons who could conceivably have moulded it to fit the pre-existing law did not have much opportunity of doing so. A survey recently presented to the Medico-Legal Society by Mr. William Latey and Mr. D. Harcourt Kitchin, barristers-at-law, showed that it fits much better on to the earlier law of divorce than on to the law of mental disorder, with which it is intimately connected through its provisions for divorce and nullity on the ground of insanity in a party to the marriage. As these authors pointed out, the number of cases in which the insanity ground is raised is small—only about a hundred and fifty a year out of seven thousand. Petitions on the ground of desertion are much more numerous. In matters of justice, however, numbers do not matter; if a statutory provision oppresses a few, it needs amendment just as urgently as if it oppressed many, and in some respects Herbert's Act calls loudly for amendment.

A petition for divorce on the ground of insanity may be presented by either spouse on the ground that the other is incurably of unsound mind and has been continuously under care and treatment for at least five years immediately before the date of the petition. "Care and treatment" is very precisely defined, in terms that sound strange to a medical ear. A person is deemed to be under care and treatment while he is detained in pursuance of any order or inquisition under the Lunacy and Mental Treatment Acts, 1890-1930; or of any order or warrant under the Acts relating to the fighting Services; or while he is being detained as a criminal lunatic or in pursuance of an order made under the Criminal Lunatics Act, 1884; or while he is receiving treatment as a voluntary patient under the Mental Treatment Act, 1930, "being treatment which follows without any interval a period of such detention as aforesaid." To make it quite clear that those cases mark the limits of "care and treatment," the section concludes "and not otherwise." Not every permanently insane spouse, therefore, comes within the Act. For instance, the section says nothing about temporary treatment under sect. 5 of the 1930 Act, by which a patient who is incapable of volition but likely soon to recover may be admitted to a mental hospital without a reception order for six months. After that time his temporary treatment may be continued for two more periods each of three months "as may be specified in directions given by the Board of Control." If, therefore, a patient is admitted to a mental hospital on the temporary footing, recovers volition within six months, and remains as a voluntary patient for another five years or more, then even if he is incurable he cannot apparently be divorced under Herbert's Act, for the voluntary treatment does not follow a period of detention under an order, inquisition, or warrant "as aforesaid." It only follows a period of temporary treatment, which, though by the Mental Treatment Act it is called detention, yet is not detention under an order. Nevertheless, if a temporary patient remains without volition for six months and then has his period of treatment extended by directions of the Board, these directions count as an order (Benson *v.* Benson, 1941); and any subsequent period of voluntary treatment is good for divorce purposes. This anomaly badly needs adjustment. So, too, if an otherwise valid period of voluntary treatment is interrupted by a period of temporary treatment, it is probably vitiated for divorce purposes because the temporary treatment, for the first six months at any rate, is not detention under an order. Again, an English patient who happens to be detained in a Scottish mental hospital does not come within Herbert's Act, just as a Scottish patient detained in an English hospital does not come within the corresponding Scottish Act. Other cases in which the care and treatment may be legally interrupted, though the insanity which is the real ground for the divorce subsists, are those in which the patient is let out for a substantial period on trial or holiday, or is discharged to relatives, or escapes for longer than the fortnight within which he may be retaken on the original reception order. The President said in Shipman *v.* Shipman (1938) that routine outings in the daytime or short leave of absence may not interrupt the detention, but that absence on trial for prolonged and indefinite periods may do so: in each case the court must decide whether an invisible line has been transgressed or not. The statutory care and treatment may also be interrupted by a purely technical mistake, such as the failure of a workhouse officer to give the certificate of suitable accommodation required by sect. 25 of the Lunacy Act, 1890, on the transfer of an incurable rate-aided patient (Murray *v.* Murray, 1940). There is no provision in Herbert's Act for divorce on the ground of mental deficiency for which a spouse is indefinitely detained in an institution.

Another legal anomaly under the Act has been introduced by an unfortunate decision of the Court of Appeal. Insanity, besides being a ground for divorce, may be a defence against a petition for divorce alleging desertion or cruelty, for if the respondent is insane he may not be responsible at law for these offences. In Williams *v.* Williams (1939) the court held that, because the respondent husband had been certified as of unsound mind, his wife could not divorce him for desertion although he had deserted her many years before his certification. Once a respondent loses through insanity his ability to form an intention to desert or to return, he no longer commits the matrimonial offence of desertion, for he has no longer the *animus deserendi* which is indispensable to the offence. Moreover, and even less justifiably, if the respondent is certified under the Lunacy Act his irresponsibility is presumed, and the petitioner is not allowed to bring evidence of his actual state of mind. A certified patient may be charged with murder, and then evidence of his state of mind is heard; he may be sued for causing damage to property, and the aggrieved person is at liberty to bring evidence showing that he was responsible; during a lucid interval he may make a valid will. In desertion alone is he presumed on the strength of the certificate to be irresponsible. This decision should be reversed by statute as soon as possible, for, apart from the hardship it may cause, it distorts the pattern of the law governing responsibility.

No amending Bill can come before Parliament until the war is over and controversial private Members' legislation can again be introduced. No doubt, however, Mr. Herbert and others will take the first opportunity of seeking to remove these and other incidental defects of an Act which on the whole has fulfilled its purpose admirably.

THE ADRENALS IN ANOXIA AND IN SHOCK

Judging from the large variety of subjective and objective symptoms observed in anoxia, it is probable that all the active systems of the body are adversely affected. Attempts have been made from time to time to attribute the main trouble to damage of one particular organ, and in this respect the adrenal gland is at the moment receiving a good deal of attention from research workers. R. A. Lewis and his co-workers[1] exposed rats, rabbits, dogs, monkeys, and human subjects for single periods of 1½ to 24 hours to mixtures of oxygen and nitrogen with the partial pressure of oxygen adjusted to correspond to altitudes of 11,000 to 34,000 feet. Their conclusion from the animal experiments is that the "carbohydrate-regulating" factor of the adrenal cortex is closely concerned with the changes in the organism during anoxia, and that it enables adrenalectomized animals to withstand exposure to an otherwise fatal oxygen tension and results in an increase in blood glucose, liver glycogen, and excretion of nitrogen. The increased excretion of potassium during anoxia appears to be accounted for by factors other than the adrenal cortex, whereas the increased excretion of sodium and chloride appears to be mediated by the "carbohydrate-regulating" factor of the cortex. Lewis and his colleagues' eight human subjects were exposed in bed in an oxygen tent to an oxygen tension of 98 mm. Hg, corresponding to an altitude of 13,000 feet, for 5 hours only. This did not cause any striking change in various blood and urinary constituents, although there was a fall in excretion of urinary nitrogen, and in one or more of them there were the following signs and symptoms: hyperventilation, tachycardia, cyanosis, frontal headache, mental exhilaration, general weakness, fall in blood pressure, syncope, precordial discomfort, nausea, and vomiting. The two subjects who lost consciousness remarked that they had similar reactions on motor-car or boat trips. The administration of intravenous glucose to four of the subjects was not associated with improvement in subjective symptoms. Also, the electrocardiographic changes during anoxia were not restored to normal by glucose, although the authors state they have evidence that changes in the electrocardiogram may be associated with abnormalities of carbohydrate metabolism.

Much research work is also being carried out in connexion with the part played by the adrenal and its carbohydrate-regulating factor in shock. H. Selye and C. Dosne[2] find that the venous blood coming from a damaged area is always much poorer in glucose than is the venous blood of a non-traumatized area in the same animal, although, usually, the systemic blood sugar is very high in traumatic shock. In adrenalectomized rats, whose resistance is low, traumatic shock is not accompanied by a rise in the systemic blood sugar, and, indeed, often causes hypoglycaemia. Active cortical hormone preparations restore to normal the low blood sugar of non-traumatized animals subjected to adrenalectomy, but do not raise it about this level, nor do they cause hyperglycaemia in intact animals. On the other hand, if such extracts are administered during traumatic shock to adrenalectomized rats, they cause a significant rise in the blood-sugar concentration, and at the same time increase resistance to shock. It appears that the metabolic changes elicited by extensive damage alter the action of adrenal cortical hormones on blood sugar. It is possible that in shock the blood sugar decreases in the absence of the adrenals because the lactic acid produced fails to be resynthesized into glucose. In any event it seems that changes in carbohydrate metabolism play an important part in the pathogenesis of the shock syndrome.

Other workers have been investigating the possible therapeutic action of cortical hormones in shock. There are a number of reports that "cortin" and corticosterone are of some benefit in treatment or prevention of this condition. Desoxycorticosterone appears to be of some value in "muscle shock," but not when the shock is due to damage to viscera. Recently R. L. Noble and J. B. Collip[3] introduced a method of producing shock in rats which they consider excludes the complication of haemorrhage in addition to those of infection and anaesthesia. The animals are placed in a revolving drum and raised up to a short distance and then dropped. This is repeated many times, and eventually this type of trauma leads to haemoconcentration and the pathological changes ascribed to shock Noble and Collip conclude that a poison or toxin is formed in the damaged tissues, muscles, and viscera, and that there are two possible types of cases. First, there is the case in which, as the result of rapid formation of large quantities of the toxic substance, death follows trauma very rapidly without much haemoconcentration. Secondly, there is the case which runs a protracted course with increasing haemoconcentration due to loss of plasma through the capillaries. In their animal experiments Noble and Collip found that the mortality was mainly toxic in nature, and they attempted to prevent the condition by pre-treatment with various cortical extracts from the adrenal gland. They got some evidence of therapeutic effect, but nevertheless conclude that from the practical standpoint the effects of adrenal preparations on this type of shock are disappointing; but they have stimulated further research. At the same time, no doubt, the difficulty is that other organs are concerned in the mechanisms not only of shock but also of the anoxia which usually accompanies shock.

SULPHANILAMIDE IN ACUTE NEPHRITIS

The close relation of acute nephritis to infections with the haemolytic streptococcus has been recognized for many years, and it is therefore tempting to suppose that drugs of the sulphanilamide series might have a beneficial action on the course of the nephritic process. With a view to testing this hypothesis Williams, Longcope, and Janeway[1] have lately compared the results in 42 cases of acute nephritis treated with sulphanilamide during the acute phase of the disease with a series of 70 cases not so treated compiled from their previous records. Sulphanilamide has been shown to be relatively harmless to the normal kidney, and has not produced the haematuria and anuria occasionally noted during treatment with sulphapyridine or sulphathiazole, but the authors state that in the presence of even slight renal deficiency the drug is not excreted as rapidly as in the normal subject and so accumulates more rapidly in the blood. The treatment must therefore be used with some caution in nephritis.

Almost all the patients treated had some focus of infection (usually the tonsils) from which beta haemolytic streptococci had been recovered. The control group was picked to represent as nearly as possible a series of cases of equal severity and of the same aetiology. The authors claim that in the treated series the foci of infection cleared up more rapidly, the duration of oedema and hypertension was shorter, and the percentage of clinical recoveries greater. Although this is true for the small number of cases recorded, a critical examination of the work under review shows that the differences in the outcome of the two groups of cases were not striking and may not have been entirely due to the sulphanilamide therapy. For instance, the control group contained a smaller proportion of cases in which oedema and hypertension were absent. Moreover, even the treated groups were subjected to tonsillectomy and other procedures for the surgical removal of septic foci. Dosage was very variable, being in some cases 1.2 g. and in others 6 g. per diem, the total amount of sulphanilamide administered varying from 9 to 169 g. Certain facts, however, seem to be indisputable. The number of cases in which positive throat cultures were obtained at the time of discharge from hospital was decidedly less in the treated group; temporary exacerbation of the nephritis after tonsillectomy was common in the untreated and rare in the treated group; and the renal function was never adversely affected by sulphanilamide, even though it was given during a stage when oedema, hypertension, albuminuria, and nitrogen retention were present. The immunologic reactions of the patients, as shown by the antistreptolysin titre of the blood serum, were unaffected. It seems safe to conclude that, whereas sulphanilamide does not constitute a cure for acute nephritis, it is a relatively safe method of treatment and should be used wherever active streptococcal infection is present, and also before and after the removal of septic foci in these cases.

WHAT THE CHILD THINKS OF SCHOOL MEALS

Doctors and educationists and social workers have given their own opinion of the school canteen and its advantages, but it has been left for the Education Committee of Hertfordshire to elicit what the children themselves think about the experiment. Under the title of "The School Child and the School Canteen" the Hertfordshire County Council has published the results of an inquiry undertaken by Mr. F. Le Gros Clark into the reactions of the children to the change in social habits which the school canteen signifies. The inquiry was carried out through the medium of the school essay, and the first 600 essays to come to hand from 19 schools in the county were analysed. About 31% of the boys and 35% of the girls expressed a preference for meals at school, and 45% of the boys and 41% of the girls for meals at home. The remainder were indifferent or had conflict of choice. Meals at home were preferred by a considerable proportion of the older children—that is, those over 13 years of age. The chief reason given for preferring meals at school was the excellence and variety of the food, but, on the other hand, those who preferred meals at home cited most frequently the insufficiency of school meals. Many of the essays were written by children evacuated from London into Hertfordshire, and it is evident from their essays that some of them concentrated upon the school canteen the resentment of the evacuated person against what he considers to be undue favour shown to the local child. Criticism of school meals, however, was fairly common. Complaint was made not only of insufficiency of food—probably the second helping by the indulgent mother is missed—but of indifferent cooking, overcrowding at tables, and noisiness. It is evident from the essays that so far there has been little imaginative effort to develop among these children a community spirit at their school meals or to deal encouragingly with the shy and nervous among them. Undoubtedly a large number of children now feeding at school—in Hertfordshire about 16,000 children are now fed every school day—do hanker after the greater freedom of the domestic table, the sense of maternal thoughtfulness, and the chance of expressing their likes and dislikes. It seems likely, whatever course the war takes, that the food situation will call for such communal service for some years to come. If so, a generation of children will pass a large part of their school life within the school-meal system. Teachers and others should therefore do what they can to transform the canteen from an improvised method of getting children fed into something which will have a formative influence on their training and be a valuable means of social instruction.

SURGEON'S MEDAL FOR LORD NUFFIELD

The medical profession will note with great pleasure that the Royal College of Surgeons has awarded its Honorary Medal to Lord Nuffield "in recognition of his conspicuous service in assisting the improvement of natural knowledge and of the healing art and of the many liberal acts and distinguished labours inspired by the desire to advance the science and practice of medicine and surgery." Lord Nuffield's benefactions have been distinguished not only by their munificence but by clear knowledge of the present needs of medicine and wise foresight of its future problems. Only recently we announced the decision of the Nuffield Provincial Hospitals Trust to create a professorship and to found an Institute of Social Medicine, devoting to this purpose £10,000 a year from its income for the next ten years. There is no need to enumerate in these columns the many other generous contributions Lord Nuffield has made to what we may call his "chosen profession." We may be sure that of the 19 recipients of the College's Medal few have deserved it so well as he.

THE HALF-YEARLY INDEXES

The usual half-yearly indexes to the *Journal* and to the *Supplement* have been printed. They will, however, not be issued with all copies of the *Journal*, but only to those readers who ask for them. Any member or subscriber who wishes to have one or both of the indexes can obtain what he wants, post free, by sending a postcard notifying his desire to the Accountant, British Medical Association House, Tavistock Square, W.C.1. Those wishing to receive the indexes regularly as published should intimate this.

SALVAGED EXPERIENCES

CASES AND COMMENTS FROM GENERAL PRACTICE*

BY

E. DOUGLAS GRANGER, M.D.

Before consigning my bombed and scattered papers to their more useful function of salvage I have extracted a few cases and comments thereon. These random reflections I present to you in the hope that they may give some impression of that pleasant backwater of medicine in which I drift—private practice in a seaside resort.

An Odd Clinical Blunder

A habit of taking notes was initiated by a curious clinical blunder that occurred before I came to Bournemouth. Early in the morning a sailor came to see me complaining of severe abdominal pain and sickness. He was also on the defaulters' list for the day, and was accordingly examined with care and suspicion. No evidence of disease was found, and he was encouraged to return to work. At 3 o'clock on the same afternoon I was in the ward room recovering from lunch when there was an urgent call to the upper deck. There I found the unfortunate sailor stretched out, ghastly white and obviously desperately ill. He had a thready rapid pulse, sunken pain-distorted features, cold clammy skin, shallow respirations, a rigid abdominal wall exquisitely tender. I concluded that I had missed a serious abdominal emergency, and ordered his removal for immediate operation to the hospital ship *China*, some four miles away. As he was being lowered over the side an elderly warrant officer approached me and said that, in his opinion, there was "nothing wrong with Bill's belly, but that he was suffering from the screws." Now, I had been long enough in the Service at that time to treat the many theories of the executive with restraint, and on inquiry I found that a very usual practical joke had been played on him when he was over the side for a slight depth at the bottom of the ship in a diving-suit. He had been blown up, which consists in being brought quickly to the surface, generally upside down—a most uncomfortable sensation. Although I did not believe that such a slight change of pressure could have been in any way responsible for this very serious condition, I reluctantly agreed to stop at the *Cyclops* on my way to the hospital ship. There we were both put in the compression chamber, with the most dramatic results, as Bill the sailor rapidly became sprightly and well, and I felt very poorly indeed. There is no disguising one's intentions in the Navy, as your diagnosis is blazoned in bunting to the entire fleet, so we had to return to the ship, Bill to his work and I to the ribaldry of the ward room.

The interesting point of this case is—first, what would have happened to the man if he had gone straight to the hospital ship; secondly, surely such a shallow diving descent could not possibly produce caisson disease in a normal man; and, in fact, this particular man six weeks later, after carrying out full duty, suddenly reported sick again, and was operated upon for a perforated duodenal ulcer.

Abdominal Surprises

Midwifery constitutes one of the most exacting parts of private practice. The following case did much to scatter my enthusiasm for it.

I was called to a primipara, aged 36, apparently in strong labour. She appeared very emaciated and ill, and although she seemed to be getting regular strong pains I could not feel any uterine contractions. It was a transverse lie. I spent a night trying to do version. The head could be manipulated into the pelvis, but it was no sooner down there than it seemed to pop up with the greatest of ease. After three hours my poor patient suddenly appeared even more collapsed than I was myself, and to my alarm I felt what appeared to be a foot immediately under the skin, and I thought that I must have ruptured the uterus. At a further vaginal examination I did at last succeed in feeling a hard small body, low down in the pelvis and below the child, and it eventually dawned upon me that I was dealing with a full-term ectopic. At the operation two days later the placenta was found to be spread out over the small intestine. A live child was removed, and survived, but attempts to remove the placenta caused the most profuse bleeding. Portions of it were cut away. The remainder was clamped, and an open sloughing wound discharging bits of placenta from the abdominal wound persisted for a couple of months.

Among the cases of abdominal conditions I was surprised how far less frequent the chronic appendix seems to be in recent years, and during the last ten years I have attached importance to the following sign: the sudden removal of the hand after fairly deep pressure in the right iliac fossa, giving a sharp transient pain. If I have been able to get that sign, coupled with *x*-ray evidence of a residue in the appendix twenty-four hours after all bismuth has left the large bowel, I have generally felt satisfied that I shall not have that unpleasant experience of trying to convince myself that the appendix is a little pink and yet having an uncomfortable feeling that the dolorous symptoms, probably due to gut spasm, will resume their appearance. Because there is not much doubt that in these days of tension the spastic bowel can simulate many serious diseases, and a little hyoscyamus with a soft vegetable bulk such as "visiblin" sometimes relieves the most apparently ominous physical signs.

Circulatory Signs in Neurasthenia

Among the most difficult of patients is the advanced chronic neurasthenic. May I recall one case.

It was that of an officer aged 40, with a brilliant war record, whose subsequent retirement brought him great disappointment. He had many complaints, varying from day to day, including numbness of the hands, pains in the limbs, occipital headache, anorexia, constipation, sinking sensations of the epigastrium, apprehension, and constant profound depression. His height was 5 ft. 11 in.; his weight 5 st. 6 lb. The asthenia and emaciation were so extreme that it was difficult to believe that there was not some gross underlying organic disease. Repeated tests and consultations with other colleagues were necessary to exclude this. An interesting sign was constantly present. The pulse at the wrist resembled the pulse of a patient *in extremis*—feeble, thready, almost imperceptible. This was a change in volume and not in pressure. The blood pressure was normal—120 maximum, 94 minimum. In marked contrast with this thready pulse were strong clear heart sounds, without any evidence whatever of heart disease. In a less marked degree I have noticed in other neurasthenic patients this combination of a thready pulse with a normal blood pressure and strong clear heart sounds, and I would submit this as a useful sign in the differential diagnosis of the neurasthenic state. Without doubt it is essential in these people to exclude the presence of any associated chronic factor of disease, such as tuberculosis, diabetes, myxoedema, or any abnormal condition of the blood.

Value of the Blood Count

In fact, apart from the urine test, I believe the blood count to be the most useful single laboratory test in private practice. I have records of two cases in which the only subjective symptom was a painful tongue with no objective symptoms or signs, and in which the blood count disclosed agranulocytosis. Anaemia is especially apt to prove a trap. It is quite possible for a severe anaemia to exist without there being any apparent signs or symptoms, apart from the blood count, and even this may be misleading, as the following case will show.

A lady patient of mine aged 50, always of a nervous temperament, developed pronounced psychogenic symptoms. She was unable to be alone at night, unable to go out alone, could not carry out her ordinary household duties, would not enter a church, was suspicious and almost paranoic concerning her relatives, felt she could not get—as she described it—on top of things, and was convinced she was suffering from some obscure and terrible disease. In order to satisfy her, many investigations were carried out, including a blood count, which was normal. Six months later, at her request, another blood count was done, and was normal. A further six months later a blood count was again done, and revealed a typical picture of advanced pernicious anaemia.

---

* A paper read to the Bournemouth Division of the British Medical Association.

This patient belonged to a family that showed a curious blending of blood and glandular dyscrasia. The eldest sister died of bronze diabetes; the second sister, after an operation for an ovarian dermoid, remained apparently well for ten years, and then suddenly died from acute haematemesis. At the necropsy Dr. McNaughtan found an enlarged spleen and scattered areas of necrosis throughout the liver, conforming to appearances due to splenic anaemia. The third sister was the one I described above, who ultimately died of paralysis agitans. One brother died of paralysis agitans and pernicious anaemia. The fourth sister developed signs of myxoedema with complete baldness and great increase of weight, and finally retention and overflow, which was relieved by removing a dermoid of the ovary and a fibroid which was pressing on the neck of the bladder. She also had a spina bifida. The fifth sister has a blood count suggesting aplastic anaemia, makes but little response to liver therapy, is bronzed in colour, and, although her blood pressure is normal, improves in health and is kept going by injections of "eucortone" (suprarenal cortex).

The only progeny of this strange family seems to have gathered all the glandular strength into his own robust body. He is a fighter pilot.

Functional Symptoms with Organic Basis

Fatigability alone may be an organic manifestation. A patient of mine leading a very active public life repeatedly sent for me complaining of one thing only—excessive fatigue. No evidence of disease was detected until I gave her gas for dental extraction. I spent a very unhappy three-quarters of an hour trying to make her breathe again. Within six weeks of this she rapidly developed increasingly advanced signs of myasthenia gravis, with bilateral ptosis, weak flaccid buccal muscles, difficulty in swallowing, and affectation of the speech, and has had to give up her Parliamentary career. I have also yet to convince her that my gas was not the cause of all the trouble.

Symptoms suggesting involvement of the basal ganglia and extrapyramidal system appear to be increasingly common. It seems to me that, in this domain of medicine, functional symptoms can easily have an undetectable organic basis. The usual criteria for differentiating functional from organic disease are not available, and it is common to meet with temporary symptoms of disorder, especially tremor. I have notes of two patients who developed quite violent clonic spasms of the trunk muscles when under any emotional stress. They are well otherwise, and I doubt if they could be classed under any definite organic disease. In this sense they are cases of functional nervous disturbance, and yet I believe they would prove suitable soil for the supervention of organic disease in the event of any great mental or physical stress. A case suggesting this is as follows:

A landlady aged 45 I knew for about ten years as a sensible, industrious, pleasant-natured woman, never ill, and very quiet in her general manner and behaviour. There was no occasion to attend her, but on visiting the house to attend other people I noticed she occasionally had a slight tremor of the trunk muscles and right hand if she was in any sort of worry. After twenty years of hard work she had saved a capital of £200. She then took to backing horses. In three weeks she doubled her capital, and in a further four weeks she had lost her winnings and her capital, and had got slightly into debt. During that period of seven weeks she rapidly developed all the signs of advanced paralysis agitans, from which she still suffers. In her case the reaction to emotion was certainly extreme.

Allied with these mid-brain affections are those curious vasovagal conditions, including Raynaud's. A lady aged 54 who had lived in the Tropics and was subject to curious vascular changes in the legs suggestive of Raynaud's disease suffered from a marked exacerbation of symptoms and violent intractable pain in the foot, which became deep blue in colour. These were followed by a profuse bullous eruption starting on the toes and soles of the feet, and then rapidly appearing over the whole body, the arms, and the face, coming out in successive crops. The bullae were rounded and tense, and were filled with clear fluid. There was a high intermittent temperature varying between 104° and 97°. She suffered intense pain and was desperately ill. Her blood showed a marked eosinophilia. She had become an undoubted case of pemphigus vulgaris.

At this stage, when she was almost suicidal, Dr. Watson Smith saw her, and with his peculiar genius for balanced applications suggested a lotion, which was continually painted on about every three hours. Although a simple thing, it was so remarkable in the immediate relief it gave that I venture to recall it.

Liq. plumbi subacet. fort.	2 drachms
Chalk	6 "
Zinc oxide	6 "
Olive oil and liq. calcis, equal parts	ad 10 oz.

This, plus 1/6 grain of morphine every three hours, was the only treatment she received, and after two months all signs of the rash had completely disappeared, and it has not recurred.

Two Cases and a Moral

Concerning bullous eruptions, a most unpleasant case that I was associated with was that of a certain lady of about 64 who suffered from chronic bronchitis. After being ill for some three weeks she suddenly developed a profuse pustular eruption of the hands, arms, feet, and face, associated with a high temperature, and a doubt arose as to the possibility of smallpox until the fact that she was taking potassium iodide was noticed. When this was stopped she made a gradual recovery, with the exception that she had the sight of her right eye permanently impaired.

A less unfortunate case concerned a middle-aged Jew whom I was asked to see as he had been sent down from London on that day as a case of Mikulicz's disease and had difficulty in breathing. I had never seen anybody so closely resemble in appearance a terrified frog. His eyes were bulging, his face was slightly cyanosed, and he had a huge, brawny, tough, oedematous, apron-like swelling below his chin, extending down his throat and obviously causing great embarrassment in breathing—so much so that the possibility of tracheotomy had to be considered. As this swelling was not confined to the salivary glands alone I could not see how it could be a cause of Mikulicz's disease, and with the pustular lady in my mind I asked to see his prescription. It contained three grains of postassium iodide. The prescription was altered, and within 48 hours, to his intense delight, the swelling had almost entirely gone and the Mikulicz's disease was cured.

An interesting point was that both these patients had albuminuria, with a few scattered casts, and in future I would always hesitate to give potassium iodide to anybody whose kidneys were in any way affected.

A Problem in Diagnosis

A strange difficulty in the differential diagnosis of uraemia concerned a certain middle-aged woman who had her right kidney removed, who complained of frequency and pain on micturition, and who had an enlarged left kidney and urine solid with albumin, and containing hyaline and granular casts. I first saw her in the morning, and the same afternoon I was sent for; she was completely unconscious and had two convulsions in front of me; in the interval she remained unconscious, with stertorous breathing. I concluded this was a case of uraemia and sent her into a nursing home, thinking she would not survive very long. The same evening, about 10 o'clock, during a game at poker, I had an urgent call to the nursing home, and when I arrived there I found pandemonium. The good lady was out on the landing. She had thrown the ornaments off the mantelpiece through the windows of her bedroom. She seemed to be in a delirious rage, and had knocked one of the nurses down, and was being held on to desperately by her husband. I am ashamed to say I got caught up in the general atmosphere of excitement, seized her by the shoulders, and said, "Get back into bed, you silly woman." She had one look at my inflamed countenance, and quietly returned to bed and went off to sleep. She showed a curious instance of alcoholic reasoning, because her unfortunate husband approached me and said, "Doctor, you are wonderful; I could do nothing with her. I went up to her and I said, 'Darling, its G—— speaking,' and she turned on me and said, 'Don't you try these bloody broadcasting methods with me.'" However, she did have a high blood urea, and some two months later died with all the appearances of uraemia.

Two Happy Endings

My limited opportunities of seeing the effects of radium have been somewhat varied. I have records of five cases of radium inserted into the mouth for cancer; all of them were disastrous in the results, and I have been left with a feeling that I should think very long and very carefully before I encouraged anybody to use radium in the mouth. But the following case does show how on occasion a wonderful effect can be obtained in other parts of the body.

A patient aged 62 was sent down from London by Mr. Hedley. He had operated on her and found that she had an extensive round-cell sarcoma of the uterus, which he was able only partially to remove, and which he considered was of a very malignant type, as it had apparently increased enormously in size during a voyage back from Ceylon for operation. She was sent down to Bournemouth really to die. I was first asked to see her because she had a severe and alarming haemorrhage, and when I arrived she had bled so much that I should have been tempted to give her a good injection of morphine and let her depart in peace, except for the fact that she was very acutely conscious and terrified, and something had to be done. Mr. Adeney dealt with her. Under gas-and-oxygen he removed with his hand masses of necrotic growth, and packed in a dose of radium, which he repeated in 48 hours. She was not given a blood transfusion, but received liver extract for her profound anaemia; and the remarkable thing was that, 14 days after this, on examination, she had a beautifully smooth vagina and no trace of any growth could be felt. She has made the journey from Ceylon every year since. I last saw her in 1939, when there was still no trace of recurrence, and I had an air-mail letter from her a few days ago from Ceylon saying she was flourishing and well—exactly 10 years after the operation. Such are the contrasts of a very limited experience.

It is always necessary to be on the look-out for residues of tropical conditions in Bournemouth. I came across records of 14 cases of relapse from tropical sprue; and in passing I would say that these relapsing cases did remarkably well and gained weight on an exclusive diet of either oranges—twelve a day—or, if possible, strawberries, and six to eight pints of colostrum-free milk, liver soup, and, recently, injections of liver extract, and nothing else. One man sent down from Windsor Clinic as a hopeless case gained 2½ st. on that diet and is now well.

One most interesting case was that of a young woman aged 32 who had recently come to England from Hong Kong. She was running an intermittent temperature varying between 103° and 97°; she was very pale and thin, and complained of intestinal discomfort, slight diarrhoea, and frequency and pains after micturition. She had a marked secondary anaemia. On examination a large irregular and apparently soft and cystic mass could be felt in the left loin. It could be pushed back into the lumbar region and was resonant in front. Her urine contained a few granular casts, a moderate amount of albumin, and a number of blood cells. A pyelogram was done and a cystoscopic examination made, but without revealing any disease of the left kidney, and in spite of the anterior resonance the question of whether this peculiar mass was a spleen came under review. The examination of her stools did not disclose anything abnormal. Dr. Bottomley, who kindly saw the patient with me, suggested the possibility of kala-azar. A sternal puncture was done without results. Finally, Dr. Cole examined altogether 14 blood films taken at separate times, and eventually found one cell with parasites. The patient was sent up to London to Dr. Hamilton Fairley. A further sternal puncture was done and Leishmania organisms found. She was treated with neostibosan, and made a slow but complete recovery. She went back to Hong Kong, and I had a letter from her this year saying she was quite well and had managed to get out of Hong Kong in time.

A Diagnostic Trap

In a practice of my type a solid block of work comprises the treatment of the chronic elderly invalid, and, indeed, some of my more intimate colleagues have suggested to me that my *magnum opus* consists in the art of holding old ladies' hands. While I admit that the occasional holding of an elderly distressed hand may be a matter of great therapeutic value, yet I always hope with the other hand to feel her breasts, palpate her hernial openings, and, indeed, explore any other suspicious orifice, because there is no doubt that the supervention of a serious or an acute condition upon a chronic malady constitutes one of the greatest diagnostic traps in medicine.

Such a trap was a lady patient of mine, aged 64, who had apparently never been very well since the change of life, who had a slightly enlarged heart, with an aortic murmur, and a highish blood pressure, and who insisted on remaining firmly in bed: nothing I could do would get her up. She remained there in placid resigned enjoyment of her various maladies, did herself pretty well, and occasionally as a result had digestive upsets. One morning she had been sick; her bowels had been opened, she did not appear ill, her pulse was regular and of good volume, and there was no abdominal distension or tenderness, and I unfortunately watched her for four precious days. During that time she was sick about three times in the twenty-four hours, did not deteriorate in general condition, and had her bowels opened each day. On the fourth day a specimen of her vomit had a definitely faecal odour, and she was removed to the private block of the hospital, where at the operation Mr. Rooke found a segment of the small intestine caught up in the obturator foramen. Only the partially trapped portion of the gut was gangrenous; the remainder appeared normal. A resection was done, but unfortunately she died with uraemic symptoms some ten days later. This is the only obturator hernia I have seen, and it is an interesting fact that it came out her sister had also died of a strangulated obturator hernia.

I always try to get a necropsy. In these days of cremation it is surprising how often one can be obtained, and in time it may become an automatic rule. The correlation of clinical signs with post-mortem findings would certainly redound to clinical knowledge. Doubtless even when all the projects of our New Planners come to their full fruition and that Utopia of organized prevention eventuates, there will still be ample material for the mortuary.

An elderly irascible man, aged 72, who had resided abroad and had evidently lived hard and thoroughly, gave all the signs of cirrhosis of the liver—alcoholic history, telangiectases of the nostrils, dropsy, distended abdomen with ascites, and, after tapping, a hard smooth liver edge that could be felt stretching across the abdomen at the level of the umbilicus. The spleen also appeared to be slightly enlarged. He always slept with a loaded revolver under his pillow, and to everybody's relief he one day had a sudden acute haematemesis and died.

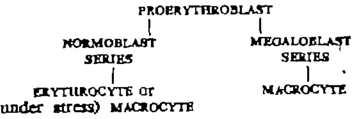
At the necropsy the diagnosis was found to be correct. The spleen was slightly enlarged to about the size that had been felt in life. He had dilated bleeding veins of the lower end of the oesophagus. He had cirrhosis of the liver; but it was the smallest liver I had ever seen—about the size of my doubled fists, tucked up high under the right cupola of the diaphragm, and could not possibly have been felt during life. What gave the sensation of that definite liver edge in life I don't know. There were no enlarged glands or thickened mesentery, and I do not think it could have been the rectus sheath, which is sometimes mistaken for the liver edge. The ascites made it impossible to discern liver dullness during life.

To-day there is a deep and worthy desire to facilitate and interlock the many resources of medical skill so that they are more readily and equitably available to all. In achieving this, some people visualize the ultimate extinction of private practice. There is one service that private practice gives which, without any feeling of undue egotism, I believe to be of the greatest comfort to the sick, and the pith and essence of sound medicine. I do not refer to clinical capacity, nor to organizing ability, nor to technical efficiency, but to that intimate friendliness, based upon mutual trust and affection, without intervening authority or intervening loyalty. This is the rock upon which any satisfactory private practice is built. I hope that, with our capacity for creative compromise, we shall succeed in weaving a similar pattern into the fabric of any new scheme.

Correspondence

Megaloblastic Anaemia of Pregnancy and the Puerperium

Sir,—Davidson, Davis, and Innes in your issue of July 11 (p. 31) group 16 cases of anaemia during pregnancy and the puerperium under the title "Megaloblastic Anaemia of Pregnancy and the Puerperium." At a time when the aid of sternal smears is sought with increasing frequency in the study of difficult cases of anaemia, it may not be out of place to make a plea for both a fuller description of sternal smear pictures and a strict definition of the terms employed. The authors have evidently satisfied themselves that in each of the 16 cases described there is adequate proof that the anaemia is megaloblastic. On this proof alone rests the validity of their claim that these anaemias are megaloblastic. Discussion demands a clear definition of the "megalobast." Unfortunately dissension exists on this point. The following diagram (after Israels) will aid clarity:



The classical megaloblast of Ehrlich is a large haemoglobinated cell with an open network nuclear pattern, and is one of a series of megaloblasts from an earlier basophil cell, the proerythroblast. A limited number of such megaloblasts arise only when the factor necessary for normoblastic maturation is lacking (as in pernicious anaemia). Such a megaloblastic marrow contains many proerythroblasts and few normoblasts. The megaloblasts are recognized essentially by their nuclear characteristics. Other workers deny these megaloblasts a separate lineage and limit the term "megaloblast" to the earlier basophil cell, the proerythroblast. A previous publication makes it clear that Davidson, Davis, and Innes follow the latter usage. For them a megaloblastic marrow is one in which proerythroblasts are numerous and more mature red cells are reduced in number.

On scrutinizing their report it is found that in 3 of the 16 cases no sternal puncture was done (Cases 3, 12, and 14). Proof of their magaloblastic type must therefore rest on indirect evidence (the peripheral blood picture and the response to liver). In Case 3 (Hb 40%, R.B.C. 1,470,000, colour index 1.33, W.B.C. 12,000 per c.mm.) 1 c.cm. of liver extract was followed by a reticulocytosis in 4 days. In this and other cases discussed it must be remembered that following any prolonged or large demand on an active marrow (as, for example, blood loss at childbirth), macrocytes may be produced by a normoblastic reaction, and that such active regeneration is accompanied by a reticulocytosis. Can one be sure that such was not the case here? Again in Case 12 (Hb 52%, R.B.C. 2,180,000, colour index 1.19, W.B.C. 10,200 per c.mm.) the indirect evidence is not conclusive; 15 c.cm. of liver were given and reticulocytosis noted after 3 weeks. In Case 14 (Hb 29%, R.B.C. 1,330,000, colour index 1.09, W.B.C. 8,800 per c.mm.) 48 c.cm. of liver were given and reticulocytosis noted 2 months later. There seems little concrete proof of a megaloblastic anaemia.

In 6 of the 7 cases seen before liver therapy the qualitative and quantitative erythroblast pictures were identical with those found in pernicious anaemia in the stage of relapse. Case 9 (Hb 48%, R.B.C. 3,200,000, colour index 0.75) contained more normoblasts than the authors would expect to find in a case of pernicious anaemia. On what grounds, then, is it included as a proved megaloblastic anaemia? May this not be an active regenerating marrow showing a normoblastic reaction? The amount of liver given was 30 c.cm. (+ iron, etc.), which was followed in 7 weeks by reticulocytosis. Is the so-called liver response an example of *post hoc ergo propter hoc*?

The remaining 6 cases are not convincing. They were first examined 2 days to 2 months after liver therapy was instituted. They showed mixed "megaloblastic" and normoblastic marrow pictures, and in one case, 13 (Hb 29%, R.B.C. 1,200,000, colour index 1.21), gave a normoblastic picture. The latter had received 42 c.cm. of liver (+ iron, etc.), and a reticulocytosis was noted a month later. Is there any proof of a megaloblastic anaemia here or is this a normoblastic anaemia responding to iron and showing spontaneous regeneration? In Case 15 (Hb 32%, R.B.C. 1,580,000, colour index 1.01) normoblasts preponderate and liver (+ iron, etc.) was followed by a reticulocytosis in 2½ months. There were similar findings in Case 11 (Hb 18%, R.B.C. 950,000, colour index 0.95). What proof is there that these are not normoblastic anaemias? Only 2 cases were seen before delivery. The usual pernicious anaemia of pregnancy clears up after pregnancy, or, as Beatrice Russell shows, even during pregnancy in the case of West African women, some of whom after a course of liver continued to term without further treatment. I feel that the work of Russell (*Lancet*, Dec. 27, 1941) deserves consideration in any publication on this subject, and I would draw the authors' attention to this interesting article.

Two conclusions emerge from this discussion. Differentiation of a megaloblastic marrow from a hyperplastic normoblastic marrow may not be easy and demands close study of every characteristic. The work of Israels in this country is of outstanding value in this respect, and his classification of the erythroblasts (as indicated in the diagram) gives the most rational and reliable approach to difficult marrow pictures. Until one terminology is accepted as a standard and its terms exactly defined, confusion of thought in haematology is inevitable. If the term "megaloblastic marrow" is applied to marrows showing an increase in proerythroblasts without further qualification, such terminology offers no clear indication either as to the cause of the anaemia or to its treatment.—I am, etc.,

Manchester. M. L. Thomson.

Oxygen Administration

Sir,—In the *Lancet* of May 16, 1942 (p. 587), Prof. R. S. Aitken and Dr. A. B. Cruickshank give some results dealing with the efficiency of the modification of my mask for oxygen administration by Drs. A. Rose and T. H. Sellors (*Lancet*, 1940, **1**, 648). These latter observers preferred to use the mask with the opening above. Four years earlier (*Brit. med. J.*, 1936, **1**, 1246), I pointed out that the mask could be used in this way and I tested it carefully in this position. Drs. Rose and Sellors seem to have overlooked this.

Prof. Aitken and Dr. Cruickshank's figures for alveolar CO_2 and O_2 under various rates of oxygen flow are similar to mine. After a year's careful trial, these observers have recommended the mask to the Department of Health for Scotland for use in hospitals and mobile oxygen units as a supplement to the supply of B.L.B. masks available for treatment of gas casualties. They state that the celluloid mask used with the opening above is the most comfortable and least disturbing apparatus that they know for the administration of oxygen, not excepting the B.L.B. mask. In every main respect my findings have been confirmed, and, therefore, I made no exaggerated claims for the mask as was stated in certain quarters.

I was ill during the time of publication of Prof. Aitken and Dr. Cruickshank's paper, and this explains the delay in my letter.—I am, etc.,

London, N.W.3 J. Argyll Campbell.

Sudden Compression Injuries at Sea

Sir,—Majors N. P. Breden, A. L. d'Abreu, and D. P. King in their article on sudden compression injuries of the abdomen at sea (Jan. 31, p. 144) make some interesting observations upon the examination of fish killed by depth charge without, however, drawing any conclusions.

Eight specimens of *Gadus morrhua* (cod) brought to the surface by a depth charge in 150 feet of water were examined, and the following facts noted. No fish came up until six minutes after the explosion, and fifteen minutes later they were still arriving at the surface. When first seen all the fish showed: (1) Prolapse of the stomach—the greyish-red mucous membrane of that organ in some cases protruding like a balloon between the jaws. (2) Prolapse of the anal canal. (3) Dehydration. The last could only be judged by comparison with the feel of the fish caught by more usual methods and by their apparent lightness for size upon the scales. (No control was available.)

Immediate biopsy showed, in one case only, a small quantity of blood-stained fluid in the coelomic cavity, and in all cases intussusception of the intestines to a greater or lesser degree into the invaginated stomach—in one case as far as the last loop of large intestine. When the intussusception was reduced there was intense congestion of the vessels in the outer coat of the stomach, and some submucous haemorrhage was visible on opening the organ. There were no other positive findings.

E. Baldwin (*Introduction to Comparative Biochemistry*, 1937) states in regard to osmo-regulation in teleostean fishes that marine teleosts, whose internal osmotic pressure is less than that of their environment, avoid desiccation by swallowing sea-water and excreting the unwanted salts by way of the chloride secretory cells in the gills. Furthermore, "if swallowing is prevented by introducing a rubber balloon into the oesophagus and inflating it the fish is unable to keep up its regulation and soon dies." I suggest that, after an underwater explosion, desiccation consequent upon inability to swallow brings the fish to the surface, where, later, it dies. Possibly, however, spontaneous reduction and recovery may occur, for fish have been observed to swim off after a time.

It seems, if the above explanation is true, that the mechanism causing death in marine teleosts has little application to human cases; and traumatic intussusception, I think, has not been described as occurring in cases of abdominal compression due to detonation in water. The cause of death in elasmobranchs seems still to be uncertain.—I am, etc.,

Self Medication and the Chemist's Shop

SIR,—Although, owing to the war, I am not yet a naturalized citizen and am still but a guest in this country, I am deeply interested in the controversy concerning the future of its medical services and in the health of the nation. Will you therefore allow me a few remarks on a question which has, so far as I know, not been mentioned in this discussion, mainly in the hope of stimulating comment by observers more experienced and competent than myself. The remarks refer to: (1) the manufacture and sale of palliatives; and (2) the position of the chemist's shop.

The public is probably by now sufficiently enlightened to know that cancer and consumption cannot as yet be cured by any known drugs. But the unlimited and indiscriminate sale of preparations *effectively relieving symptoms* constitutes, in my humble opinion, a constant injury to the nation's health and probably causes many deaths. To give only two examples. (*a*) Scalding and frequency of micturition are symptoms of a cystitis which may exist by itself, or, e.g., accompany early tuberculous kidney, renal calculi, carcinoma of the prostate or bladder, or be the precursor of an ascending pyelonephritis. Good "kidney and bladder pills" will temporarily relieve the symptoms and will do so in repeated attacks until the underlying condition produces gross effects and brings the patient at long last to the doctor when the condition has become incurable or at least has caused permanent damage with prolonged incapacitation. (*b*) The same applies even more obviously to the syndrome of "indigestion." The patient will successfully "cure" his symptoms until one day his ulcer produces a severe, perhaps fatal, haematemesis or a perforation, or until his carcinoma has become inoperable.

The more effective the preparation the more dangerous it is in the hands of the patient without medical supervision. How many patients die yearly or become seriously ill for long periods by the indiscriminate use of palliatives for undiagnosed conditions? We know that a large proportion of successful research work has been initiated by pharmaceutical manufacturers, and that dramatic discoveries have come from the laboratories financed by them. We are duly grateful. But the men who carried out the research work could have had equal or better facilities if the State would build and maintain such laboratories out of the millions of pounds it could save by preventing loss of life and of working hours caused in the manner described.

The chemist in his shop is to-day the arbiter for a surprisingly large section of the population on the question whether or not a doctor should be consulted, and therefore, in some cases at least, on whether the patient's trouble will be correctly diagnosed and, if possible, cured. An unbelievably high proportion of patients from all except the very rich classes first "consult" the chemist in the hope of being given a remedy without having to pay the doctor's fee. I have no grudge against the individual chemist; the few of them whom I know are honest and conscientious. But the whole dangerous situation is aggravated by the fact that many doctors still supply their own medicines, thus becoming direct "business competitors" of the chemist. Inevitably a chemist who refuses to sell a preparation to a patient and sends him to a dispensing doctor deprives himself of a customer. Supposing even that the chemist had the knowledge and facilities for correct diagnosis—over the counter!—can one expect him in every case of doubt to send his customer to his business competitor—the dispensing doctor?

I can think of only one way to remove the pharmaceutical chemist from his embarrassing position (which has developed through no fault of his own), but it would be drastic and unpopular, and would need legislation. This is to restrict the free sale of drug preparations in open shops to cosmetics and other toilet goods; to forbid "counter-prescribing"; to require a doctor's prescription for the dispensing and sale to the public of all medicaments; and to confine the retail trade in drugs to qualified pharmacists and their bona-fide assistants. It is lawful for general practitioners to supply medicines; and in rural districts, or in emergencies anywhere, there may be no one else at hand to do so. But the medical profession could co-operate with the pharmacists and earn their good will by a self-denying ordinance to abstain from competition in the routine dispensing and supply of drugs, etc., in populous parts of the country.

The only serious opposition to the very necessary reforms would come from the vested interests of the industry, and only energetic parliamentary action could hope to be effective in achieving the proposed change.—I am, etc.,

Nottingham E. L. LOEWENTHAL, M.B., B.S.Lond.

Amoebic Liver Abscess

SIR,—Quite a number of papers and short articles on this condition have been published in the *British Medical Journal* and in the *South African Medical Journal* during the last year or two. Mostly the question was raised whether open operation or aspiration, both combined with emetine treatment, would give the more satisfactory results. In only one instance do I remember a very definite opinion given to the effect that emetine treatment alone without any surgical intervention at all would be safer and at least as successful. I have only treated a limited number of cases (9), but the emetine treatment alone has given such excellent results that I should like emphatically to support this opinion.

My first and most advanced case illustrates the point very well. The patient had a huge swelling protruding in the epigastric region and dullness on percussion over the lower half of the right chest at the back. *X*-ray examination showed the diaphragm to be pushed up high in this region. The epigastric swelling was incised and a big abscess drained. Exploration of the abscess cavity made it obvious that the swelling further back in the liver must have been caused by another big abscess. I felt uncertain whether there were one or several more abscesses in the liver and abstained from further surgical intervention. On emetine treatment the big swelling shrank with such amazing rapidity that I decided in future to use emetine only.

All subsequent cases showed striking improvement of the general condition and fall of temperature in 3 to 5 days with emetine treatment only. In most cases the swellings could scarcely be felt as distinct lumps after about 14 days. I think a "safety" emetine course 2 to 3 months later is advisable. One patient who did not come for a second course had a relapse after a few months. Another case had been treated elsewhere by open operation: relapse was cured with emetine injections.

Aspiration can scarcely be free from such dangers as infection of the pleural space, injury of adherent bowels, or mixed infection. Perhaps only in an extremely "toxic" patient, in whom one big abscess is diagnosed, aspiration might be justified. I fail to see the value of repeated aspirations. The cavity is bound to be under negative pressure after aspiration and to fill up again with serum, blood, or purulent matter until it can be closed by the healing process.

There is ample evidence that any toxicity of the contents of the abscess disappears speedily with emetine treatment.—I am, etc.,

Grootfontein, S.W.A. R. W. J. SCHEEL.

Denis Browne Technique in Talipes Equinovarus

SIR,—The Denis Browne method of treatment of congenital talipes equinovarus is considered highly satisfactory by a large number of orthopaedic surgeons in this country. Its merits are now being recognized in America, but the published descriptions of its employment as modified by individual surgeons must alarm those who know how adequate the original method is in every way and upon what sound mechanical principles it is based. Thus an article in the April number of the *Journal of Bone and Joint Surgery*, based upon a comparatively short experience of 2½ years, describes extensive modifications, none of which appears to be justified. The side bar of the splint has been reduced to rudimentary proportions, felt wedging is no longer used, and the splint is heavily padded with sponge rubber. The sole-plate has a narrow backward prolongation which must play havoc with the bedding when the infant kicks vigorously. The feet are simply strapped to the splint, without any of the repeated manual over-corrections that are such a fundamental feature of the original treatment, and which have been found so necessary in this country.

I am convinced that this method of treatment would fail to obtain good correction in a high proportion of the cases seen in England, and I would urge that those who have to treat this deformity should give an extended trial to the exact technique of Mr. Denis Browne before introducing variations.—I am, etc.,

Stanmore. K. I. NISSEN.

Medical Planning

SIR,—A meeting of the Middlesex Panel Committee was recently held to discuss the interim report. Only the remnants of that committee were present, for many of its members, the youngest whose advice and opinion would have been so valuable, were away on national service. The committee wisely agreed that under such circumstances no authoritative decision could be given.

I was very much perturbed at the conservatism that was revealed in the subsequent discussion. Even so mild a resolution "that group practice be a feature of any future service" was negatived because those present were so afraid that this might be the thin edge of the wedge leading to the dreaded State service. No. 5 (*a*) of the "Questions for Discussion" in the report was agreed to with only a few dissentients.

I did not expect a salaried State service to be agreed to, although I voted for this. What I actually advocated was really a modified State service, as one of the members pointed out; on reflection I think he was correct. I advocated a system of group practice wherever this was possible, such groups working at health centres provided by the responsible authority. Space will not permit details of these health centres, some features of which should be obvious to all. Here, and at their homes, the doctor would attend such families as had chosen him. Such centres would be governed by committees of lay and medical men, while that part dealing with medical treatment by medical men only, in a similar way to the county committees for the National Health Insurance at the present time. Certain modifications are, however, essential. I had hoped that by some such method the general practitioner could be brought into close touch with both hospital and public health work, and that his work would gradually change so as to include the maintenance of health of those trusted to his care, not merely its attempted cure when broken down. Such views, however, were not tolerated by the members present; they did not wish to be disturbed.

If this is the opinion of the majority of the profession throughout the country, some very important questions arise. There can be no doubt that the period succeeding the war will be one of reconstruction, of economic planning, and of greater socialization. The muddled conglomeration of health services that have gradually arisen, without any definite plan or direction, will not be tolerated. The health of the nation as a whole must come under one control. If we advocate the extension of National Health Insurance to dependants and to those of like status, to include consultant and specialist service (the same people having a right to hospital service), the Government will be providing for 90% of the population. Is it at all likely they will do all this and not insist on a higher standard of work, better organization, and greater control?

Why bury our heads in the sand and wait for the tide to overwhelm us? Let us formulate our own scheme of reform rather than have one thrust upon us. The scheme outlined by the question No. 6 in the interim report is a good one, although I personally think it will need State authority and financial backing to put it into practice. It is of paramount importance that as a body we come to an agreement between ourselves; that that agreement should be accepted by 90% of the profession; moreover, it should be one which is possible for the Government to accept. Let us not be afraid to discuss the salaries we are prepared to accept and the conditions under which we are prepared to work. Unless we can agree upon this we shall find a Government scheme suddenly confronting us, resulting in divided counsels and a difference of opinion, as in the case of the recent National Health Insurance extension. The result can only be disaster and defeat.—I am, etc.,

Wealdstone. J. E. GAZE.

SIR,—Although filled with admiration for the manner in which the Medical Planning Commission in its interim report has tackled the multitude of problems with which it has been faced, I must confess to some considerable uneasiness owing to the fact that these vitally important matters are being discussed at this particular time. No one knows what the "brave new world" for which we are planning is going to be like, and it is only too likely that any regime now adopted may be completely impracticable under post-war conditions.

I am quite unable to derive any comfort from the assurance, given in italics in para. 4 of the introduction, that the Commission will not consider the recommendations "until the profession has made known its views through the usual channels." To what proportion of the profession are these "usual channels" still open? It is surely realized that the majority of the younger members for whom these recommendations have been made are now serving with H.M. Forces, either over-seas, when a letter such as this would take months to reach this country, or else under conditions where it is impossible for them to attend their local B.M.A. meetings and discuss these momentous questions with the colleagues with whom they hope to work after the war.

It is just this section of the profession who will have the most definite ideas regarding the advantages and disadvantages of a State Service, which, they quite rightly realize, would have many points in common with the medical services of the Navy, Army, and Air Force to which they are now giving the best of their professional skill. It must therefore be made clear that any decisions which may be reached by the Medical Planning Commission before the end of the war will have been made without a large and important section of the profession having been consulted. This is surely a most unjust state of affairs and quite contrary to the intentions of the Commission as shown in the report, where consideration is given to the interests of all parties when viewed from a peace-time standpoint.—I am, etc.,

H. L. HOFFMAN.

SIR,—In planning good health for a people the first essential seems to be an outlook that can view the question after it has been shorn of all considerations except the doing of what is best for the common good of all sorts and conditions of people. Such purity of purpose is not so simple as it sounds. Human nature is such that altruistic endeavour, even in the best of us, is apt to be tinged to some degree, perhaps almost unconsciously, by self-interest. Such a tendency would be checked by having suitable representation of the lay population to share in the planning. After all, the masses for whom a scheme is being planned ought in fairness to have a good say in its early construction. Having agreed upon a plan in principle, then it should be possible to ensure that the terms of its application allow for equitable adjustment as regards the status and financial position of medical men, in whatever branch of the profession they serve.

Clear vision seems likely to be dimmed even more by traditional thinking, which has had disastrous effects in other spheres of national conduct, and is not conducive to success in a rapidly changing world. Much emphasis has been laid on treatment, whereas a vigorous constructive policy based on the prevention of disease is needed; in other words, there should be a biological rather than a pathological outlook. The possibilities of such a policy have been clearly demonstrated by the findings of investigators at the Peckham Health Centre. Mass radiography, which is on the way to being a recognized procedure, should do much to enlighten public opinion as to the value of forestalling active disease, and the opportunity offered by this awakening should not be lost.

Lastly, the relation of sociological factors to mental and physical breakdown should not be forgotten. Medical planning should ensure a close association between actual treatment and the application of measures for the betterment of an industrial or home environment that has led to the loss of health.—I am, etc.,

Northampton. N. B. Laughton, M.B.

Planning Commission's Report

Sir,—I fear it is too much to hope that Dr. Learoyd's letter will be read by that doubtless earnest body the Medical Planning Commission. Yet has any one of them any personal experience of country practice? Does even one of them realize the complete difference between town and country conditions? Take just one point—the ratio of visits to surgery attendances; mine often runs as high as 4 or more to 1, and on a 3-months test last summer averaged 2.5. We have no trams, tubes, or 'buses to bring the lame, the blind, and the aged to us, and one additional reason for choice of doctor is "does the baker's van run that way to fetch along the medicine."

It is not only in medical matters but in so many other town-governed activities (A.R.P., rationing, N.F.S., etc.) that we country dwellers are having the realization forced on us that all this planning, all these rules and regulations are made for urban existence and closely populated areas, that many of these schemes only fit the rural way of life where they rub, and cause endless waste of time and material with hypothetical benefit. Further, as Dr. Learoyd so rightly points out, a look at any map of any county will show how many hundreds of villages there are and how many dozens of towns.

Social areas are mainly created by physical features, not by county or borough boundaries. It is crazy to have to send throat swabs 50 miles by post when there is an excellent laboratory 5 miles away; or to assign a village for rationing to a town where none of the village's inhabitants ever go or indeed in these days can go. The town-trained bureaucratic mind just cannot understand that, however.

So when the M.P.C. gets down to its next session could it just spend some time trying to visualize the work of those thousands of doctors who live and serve outside the towns? It will benefit the patients as well as the profession. And for any sake let us keep our house free from political bias or control.—I am, etc.,

Newton Ferrers, S. Devon. W. F. Bensted-Smith.

Nurses in Hospital

Sir,—I am profoundly shocked by the letter of Dr. S. L. B. Wilks, in which he says "the brutality of matrons (and sometimes of sisters) to their nurses is notorious." I wonder does Dr. Wilks know of one single case of "a brutal matron" at the present time, or is he thinking of an isolated case or two in the past of a matron who was, perhaps, too harsh and narrow in her discipline. Surely if Dr. Wilks does know of such a case it is his public duty to bring it to the knowledge of the chairman of the hospital concerned for investigation.

In my own, rather wide experience I have found that all the improvements in conditions for nurses have come through recommendations of matrons to their committees, and that the anxiety of the matron for the well-being and happiness of the nursing staff takes second place only to her thought for the well-being of the patients. The greatest worry a matron can have is the serious illness of a member of the nursing staff. Apart from what I feel is a most unjust assertion, these statements make the work of matrons more difficult than it is already. Moreover, it is apt to be bad for recruitment to training and thereby does the health services of the country much harm.—I am, etc.,

Helen Dey,
President, Association of Hospital Matrons

Sir,—The shortage of nurses, both in quantity and quality, is a subject which is necessarily exciting much attention at present. Many suggestions have been made for remedying the shortage, and in particular criticism has been levelled at nurses' homes, the schoolgirl atmosphere engendered by them, and the petty tyranny exercised by members of the administrative hospital nursing staff.

My intention in writing is to propose that the nurses' training schools should be affiliated to a university, and that nurses who have completed their training and the necessary examinations for State Registration should receive a B.A. degree of that university. In this way the social and intellectual status of nurses would be considerably raised: parents would know that their children were receiving a university education and would be more likely to encourage their daughters to enter the profession. This university affiliation would be more satisfactory if it were something more than a nominal one and allowed for some lectures—e.g., in anatomy and physiology—with the members of other faculties and in any case for a social intermingling with them. In certain nursing schools, however, remote from universities, the principle of external studentship would have to apply.

No doubt the universities would insist on some form of qualifying or matriculation examination, and this would at first tend to limit candidates. I do not envisage that all nurses would or could undertake the course, and a percentage of assistant nurses (unqualified) would still be required, but these would, I think, diminish as time went on. The initial difficulties in working out such a scheme might be great, but I submit that it is one well worthy of consideration and for which the time is ripe.

These views are my own and not necessarily those of the authority I serve.—I am, etc.,

Colindale Hospital, N.W.9. W. E. Snell.

Sir,—I have followed with interest the recent correspondence in your columns about the difficulties and troubles besetting the nursing profession, but so far I have not seen any suggested cure that really gets down to the root of the matter. In my view the present system of training nurses has got to be changed from an apprenticeship to a trade to an organized teaching of a profession. The position to-day is remarkably similar to that of the medical profession in the middle of the nineteenth century.

How many times, in the course of her training, does a nurse have to take a temperature, make a bed, or handle a bed-pan, and how few times does she require to become proficient in these arts? Likewise, how few times does she give a hypodermic, set up a subcutaneous drip, or assist at a transfusion? Contrast the hours of cleaning and polishing usually demanded of her with the scanty time allotted to lectures and demonstrations, crammed in between tours of ward duty and frequently abbreviated by delays in theatre or ward. In other words, the real evil lies in the fact that the probationer nurse is first and foremost a servant of the hospital she is training at and only secondly a student.

Now I should like to advocate an arrangement similar to that followed in the training of medical students. There would be a number of training schools, each independent of but attached for practical teaching to a large hospital. By preference these would be the larger non-teaching voluntary hospitals and the municipal and county hospitals, as the teaching institutions already have their educational facilities sufficiently occupied. The young nurse-to-be would attend one of these schools, and, during her first year or fifteen months, would be well grounded by means of lectures, demonstrations, and practical work, in anatomy, physiology, pharmacology, and the handling of drugs, dietetics, and nursing practice. In the last half of this period a series of short demonstrations would be held at the hospital, chiefly to acclimatize the pupils to the hospital atmosphere. After passing an examination in these subjects the student nurse would then start a second year's work in which she would spend half her time at the school on surgical and medical studies and in learning how to give the more complicated treatments expected of a nurse, and the other half in ward work at the hospital. But not, be it noted, doing night duty, theatre duty, or polishing trolleys. A final examination would pass the girl out as a trained nurse, ready to be absorbed, either by her own hospital or by one where teaching was not undertaken.

As to the financial side, the school of nursing would be partly supported by grants from the State, either direct or through the College of Nursing, and partly by fees from the students. These would be low, and scholarships in ample numbers would be provided for poorer girls of promise. During the second part of the training the hospital would pay a small salary for the services of the students, and, on passing out as trained, the nurses would command a proper living wage.

While studying at the school the girls would be allowed to make their own living arrangements, and their spare time would be absolutely their own and in no way under the supervision of the school authorities except in the broad sense in which a university keeps an eye on the public acts of its students. They would be encouraged to form societies and to organize a joint social life, and in most cases a hostel would be provided for those students who could not live at home and did not desire to live in "diggings." This hostel, however, would be under the charge of a matron or warden quite distinct from and independent of the matron of the hospital and the principal of the school. Trained nurses wishing to take up theatre, maternity, or district nursing would return to the school for a further theoretical course followed by a practical course at the hospital, becoming entitled to a special diploma after a test.

If this scheme were adopted hospitals and patients would benefit in that all the nurses actually working would have had a fair amount of training. Nurses would benefit in that, instead of four years' hard drudgery on a pittance of a wage, they would be sure, after a short course of about two years, of an ample range of appointments at a decent salary. Parents also would be able to let their daughters take up the profession secure in the knowledge that the training was short and that their children would be happy in well-run hostels free from that petty tyranny which unfortunately so very often overshadows the present system.—I am, etc.,

Wimbledon, S.W.20 A. HOBSON.

SIR,—Dr. S. L. B. Wilks of Colwyn Bay (July 18, p. 84) writes that the "brutality of matrons to their nurses is notorious." In the issue of Aug. 1 Dr. T. C. Mackenzie writes from Inverness that "matrons throughout the land are loyally and ungrudgingly caring for the welfare of their nurses and probationers."

Dr. Mackenzie has spent his distinguished career associated with mental institutions between Edinburgh and Inverness, and it is difficult to see how he can speak with any authority on hospitals throughout the land. The apathy of those members of the medical profession associated with hospitals is responsible, in great measure, for the present unsatisfactory conditions for nurses. There are few members of the visiting medical staff of a hospital who, like Dr. Wilks, appreciate one of the main defects in the present nursing services. There are many like Dr. Mackenzie, who know little or nothing of a nurse's hospital life.

The tyranny of some matrons, the petty restrictions, long hours, and the limited and often inconvenient off-duty inflicted on nurses have brought almost to bankruptcy a noble profession.

All the exhortations of Mr. Ernest Brown will not bring recruits into the nursing services unless there is a rapid and effective change of nursing conditions in most hospitals. Dr. Wilks's letter contains too much of the truth to be ignored, while Dr. Mackenzie in his letter has allowed his indignation and misguided chivalry to assume the voice of experience and authenticity.—I am, etc.,

Manchester R. SYDNEY DAVIDSON.

[This correspondence is now closed.—ED., *B.M.J.*]

Phenol and Camphor for Desert Sores

SIR,—As Capt. H. M. Rapport, in his interesting article on desert sores (July 25, p. 96), does not mention a form of local treatment I found almost universally effective in this condition in the Sudan, I give it in case he, or others working in the Tropics, may find it useful.

Liquid carbolic acid 30% in camphor is applied on dry gauze once a day with a cotton-wool covering. For some unexplained reason, carbolic in combination with camphor is not toxic up to strengths of 50% so long as it is not in contact with water. For this reason the skin should be dry when it is applied, and the dressing should not be covered with strapping or a waterproof covering which would retain sweat. Sores thus treated are usually clean and healing in a week.

Incidentally, I see that the 50% strength of the same preparation is now widely used in the United States for mycotic infections of the feet. The liquid is easily carried in a small bottle, and can be applied on any dry material, not necessarily sterile, so that it is an eminently practical form of treatment for field use.—I am, etc.,

C. GRANTHAM-HILL,
Beccles, Suffolk Late Senior Surgeon, Sudan Government

⁂ The *Journal of the American Medical Association* for June 27 this year contains a warning against "the promiscuous and unsupervised use of equal parts of phenol and camphor in the treatment of 'athlete's foot.'" The U.S. Food and Drug Administration has stated that "a mixture of equal parts of phenol and camphor is capable of producing necrosis. . . ." To conform with food and drug legislation in that country, this preparation, under certain circumstances of sale, has to bear a label to the effect that it "should not be applied to damp skin or over extensive areas; should not be applied under a bandage; and that if, after use, the skin turns white or is otherwise discoloured, use of the preparation should be discontinued immediately unless the physician directs otherwise."—ED., *B.M.J.*

"Positive Health"

SIR,—The present interesting discussion of the meaning of the term "positive health" and the advisability of its use if it is to mean "exuberant health" suggests that an important factor is being overlooked. Obviously, as Mr. Wilfrid Adams points out, we cannot in a generation, nor indeed in a century, achieve exuberant health for all. Neither, however, can "we" achieve the much less ambitious aim of mere "health for all." One is reminded of a phrase from a *Times* leader of nearly 100 years ago concerning the sanitary reforms of Edwin Chadwick: "We prefer to take our chances of cholera, and the rest, than to be bullied into health." Individuals need all the guidance and reparative work our profession can offer, but by their own freely given co-operation and effort alone will they achieve or keep their health.

This raises the whole question of health education. There is little point in discussing whether it should be promoted or not, because it does in fact exist—every time a grandmother repeats an old wives' tale or a firm advertises a patent medicine. The problem is rather to find out how best to begin to eliminate the very considerable amount of bad health education, and to direct and co-ordinate the good, which is now also of considerable and growing bulk. As the bad can only be eliminated by substituting something better, the question resolves itself into a discussion of what "good health education" is and what it should endeavour to do.

There are doubtless, and rightly, many shades of opinion. I would like to suggest that it cannot be too clearly emphasized that health education is a function of preventive medicine only; in fact, one of its most formidable tasks is to eradicate the pernicious habit of self-treatment. We must not, however, confuse the curative and preventive aspects of medicine with the quite different distinction between private practice and public health. In each of these to-day both aspects are found in some degree, and one of the most desirable developments of the future may be in the growth of the educative work of the family doctor. Commercial propaganda, however regretted, gives us something of a lead as to what health education should try to do. It should, surely, "create a demand," persuade and help people to acquire a taste for health. The means by which this may be attempted are too numerous and their relative values too controversial to be discussed here, but two lines of approach may be mentioned. First, good personal and community health habits should be inculcated in schools and clinics and surgeries, but primarily in homes. Secondly, the desire for healthy environmental conditions should be developed by making such conditions accessible to all. These are undoubtedly Utopian as immediate achievements, but that seems no argument against advancing them as aims. It is apparent at least that some clearly conceived and co-ordinated policy of health education is an essential part of any medical service directed towards the achievement of health of positive, or indeed any other, degree.—I am, etc.,

Herbert S. Davies.

Gravesend.

Sir,—I envy those of my professional brethren whose agile intellects are so satisfied that they understand exactly what is meant by "positive health" that they are prepared to devise a system for its attainment. I see from my dictionary, which is beginning to disintegrate from long use, that "health" is defined as "that state of a being in which all the organs are sound and in proper condition," to which I would add "and functioning normally"; and I cannot conceive a more desirable condition. The same tattered dictionary tells me that "positive" means: "Position. Definitely laid down or expressed. Explicit. Opposed to implied. Not admitting any condition or discretion. Express. Absolute. Real. Existing in fact. Not negative. Confident. Fully assured. Dogmatic. Demonstrable. Distinctly ascertained. Over-confident in opinion or assertion."

One might be pardoned for thinking that we ought to be satisfied to strive so far as we are able to achieve and maintain a state of just plain "health" as defined above for our patients. Many of us have been so striving throughout our professional careers. But *positive* health! Let us take care that it shall not come to mean: "The state of a being which complies explicitly with the official specification definitely laid down and expressed by the Minister of Health. Such compliance must be absolute, real, confident, fully assured, dogmatic, and demonstrable, and nothing in this regulation is to be interpreted as admitting any condition or discretion or permitting any departure therefrom"; followed by a table of penalties to be inflicted on the doctor who by negligence or default fails to prevent any deviation from the Government specification. Which is absurd.

Perhaps my old dictionary may be obsolete, but even so I rather like "over-confident in opinion or assertion."—I am, etc.,

Brookwood, Surrey. H. M. Stanley Turner.

Incidence of Breast-feeding

Sir,—I was interested to read the article on breast-feeding by Dr. Enid Hughes (July 18, p. 69). For a period of 2 years in a working-class district (Port Glasgow) I collected figures on this point: infants breast-fed 128; breast-feeding plus complementary 23; breast-feeding for 2 weeks 96; breast-feeding for 2 months 67; Ostermilk 48; cows' milk 56; Cow and Gate 1; Nestlé's 7; Sister Laura's Food 7; total 433.

The average number of mothers who continued over the 2nd month to breast-feed their babies was only 33% of the total attending the clinic. The cause of failure in breast-feeding was illness of the mother in 15 cases (pleurisy 1, tuberculosis 2, chronic nephitis and debility 1, anaemia and general weakness 3, and acute mastitis and cracked nipples 8).

The majority of the mothers stated that when they came out of hospital or got up to do their housework the "milk left them." The mother was often overworked and tired, and, following the advice of friends, put the baby off the breast as the child was cross after she returned from hospital. Once a bottle was substituted for the breast, there was no difficulty in weaning the baby.

Some mothers have no desire to pursue breast-feeding even though they have been instructed at the ante-natal clinic and at the maternity hospital, and immediately they are away from the supervision of the nurse they bottle-feed the baby, still having more faith in the amount of milk to be seen and measured in a feeding-bottle than in their own supply of breast-milk. By the time the mother manages to come to the clinic, about the 3rd or 4th week, the milk supply has ceased or is small in amount, and the mother is firmly convinced that her baby is more satisfied on the bottle. It seems to me that it is when the mother is left alone without a nurse after the 2nd week that the difficulty begins. The foregoing seems to point to more home visiting daily after the 2nd week either by the midwife or the health visitor, so that the mother can have the advice and necessary encouragement to breast-feed her baby. As well as instruction to the mother at the ante-natal clinic evening classes on mothercraft and nursing could be included in the night-school curriculum, and girls in the upper classes could be taught more of this and domestic science at schools, for many girls marry while still in their teens.—I am, etc.,

Glasgow. Grace McLintock, M.D., D.P.H.

The Rheumatic Lung

Sir,—I was interested in the allusion by Dr. James Burnet (June 27, p. 804) to the fact that he was the first to call attention to the rheumatic lung. I have read Dr. Eli Davis's reply, (July 25, p. 113), in which he has pointed out chapter and verse that A. E. Garrod had already alluded in 1890 to the rheumatic "poison" as an occasional factor in the cause of pneumonia. In 1889 I was house-physician to the late Dr. Wm Howship Dickinson at St. George's Hospital. He then taught—I have often heard him dilate on the theory—that rheumatic pneumonia was one of the clinical forms of that disorder. He always stressed that in this category the pneumonia was usually bilateral and generally accompanied by pericarditis, and the prognosis fairly good.—I am, etc.,

Beaumont H. Comerford, M.D., D.P.H.

Tolleshunt Darcy, Essex.

Obituary

We regret to announce the death in his 88th year of Sir Walter Schröder, K.B.E., whose long and valuable service as coroner brought him into friendly contact with generations of medical men. His participation in coroner's work began in 1870, and in 1894 he was made deputy coroner for Central Middlesex; soon afterwards he became deputy coroner for South-West London and Surrey and held that post till 1899, when he was made deputy coroner for Central London. He succeeded to the senior post in 1910 and remained at the Central London Coroner's Court until his retirement in 1930. During his 60 years' service it was estimated that he had taken part in 50,000 inquests. Sir Walter was for many years honorary secretary of the Coroners' Society of England and Wales, and later its president; he was also honorary treasurer of the Medico-Legal Society.

Dr. James Edward English of West Hartlepool died recently in Hartlepools Hospital, where he had been a patient for the past 10 months. He was born at Kingstown, Co. Cork, in 1885, and studied medicine at University College, Cork, and in Dublin, graduating M.B., B.Ch., and B.A.O. of the Old Royal University of Ireland in 1908. In the following year he took up the post of house-surgeon at Hartlepools Hospital, and later, when he had begun private practice, he was appointed to the honorary surgical staff of that institution, in the work of which he continued to take a keen interest, succeeding the late Dr. A. W. G. Pearson as senior surgeon. Dr. English was chairman of the Hartlepools Division of the British Medical Association in 1925–6.

The following well-known medical men have died abroad: Professor Hans Hunziker, director of the Basle Health Office, aged 63; Dr. Paul Clairmont, formerly professor of surgery and director of the surgical clinic at Zurich, aged 67; Dr. Howard Morrow, ex-professor of dermatology at the University of California and ex-president of the American Association of Dermatology, specially known for his work on leprosy, aged 68: Prof. Kurt Brandenburg, editor of the *Medizinische Klinik* since its foundation in 1904, aged 73; and Prof. Albert Döderlein, the eminent gynaecologist, formerly professor of gynaecology and obstetrics at Munich and a pioneer in the bacteriology of the puerperium, aged 81—his name is attached to the non-pathogenic organism of the vagina.

Universities and Colleges

UNIVERSITY OF OXFORD

At Congregations held on July 18 and 25, the following degrees were conferred:

D M.—J M L. Burtenshaw

M.CH —A H Hunt, R. H Gardiner.

B M , B.CH —M. H. M Gilbertson, J. F D. Frazer, D. S. Parsons, J. L. Boldero, J. D Little, R F. B Bennett, Q. J. G Hobson, W. D. M Paton, W. A. Briscoe, H. G Farquhar, J. D. Green, J. Pinching, K. W. Lovel, S. L. H. Smith, *J. M Jefferson, *H J. C. J L'Etang, R. H. Scott, R. Bryce-Smith, P J Crerar, D M. Hamilton, R. Powell, D A. McDonald, N. G. D Campbell, R H Jackson, A. K. Tyler, A. M. M. Wilson, E. Shephard, W. B. Armstrong, E. L. H. Jones, G A. Neligan, C. P. Silver, J. J W. O'H. Tobin, Constance M. Ormrod, *M. R. Mullins.

* *In absentia.*

UNIVERSITY OF LONDON

UNIVERSITY COLLEGE HOSPITAL MEDICAL SCHOOL

The following scholarships, exhibitions, and prizes have been awarded:

Goldsmid Entrance Scholarships: (1) D. A. G Galton, Trinity College, Cambridge. (2) J. L Crammer, Christ's College, Cambridge *Goldsmid Entrance Exhibition* Miss J Whitham, Newnham College, Cambridge. *Filliter Entrance Scholarship in Pathology*. J. D. Judah, St John's College, Oxford. *Atchison Scholarship* · J M. Wilson. *Magrath Scholarships*. Surgery, D I. Williams; Medicine, Miss G R Briggs; Midwifery, E W. C Buckell *Filliter Exhibition:* N. Myant. *Erichsen Prize:* Miss G. M. Howard. *Liston Gold Medal:* J. A V. Bates, Miss A M. P Snow. *Fellowes Gold Medal:* W D. M. Paton, H. E Thomas. *Fellowes Silver Medal:* Miss Joan Hardy, A. N. Smith, Miss S. M Howard *Wilfred Trotter Medal:* Miss G. M Howard. *Suckling Prize in Obstetrics and Gynaecology*. P. E. Hughesden.

ROYAL COLLEGE OF PHYSICIANS OF LONDON

At the quarterly meeting held on July 30, with Sir Charles Wilson, President, in the chair, the following were elected officers for the ensuing year: *Censors,* H. Letheby Tidy, A. G. Gibson, G. E. S. Ward, Geoffrey Marshall; *Treasurer,* C. M. Hinds Howell; *Registrar,* H. E. A. Boldero; *Harveian Librarian,* T. H. Arnold Chaplin; *Assistant Registrar,* A. A. Moncrieff.

The President announced the award of the Moxon Medal to Prof. L G. Parsons for his observation and research in clinical medicine, especially in paediatrics; the Weber Parkes Prize to Prof. G. S. Wilson for his work on tuberculosis; and the Murchison Scholarship to H. J. Anderson, M.B.

Membership

The following candidates, having satisfied the Censors' Board, were elected to the Membership of the College:

A. R D Adams, M.D., H S Banks, M.D , R. Daley, M B., J V. S. A. Davies, B M , J. Denfield, M.B , J. R Dow, M.B., R. M. Evans, M.B , J. E (O'Neill) Gillespie, M D., I R. S. Gordon, M.B., E. R. Gubbay, M B , F. W Gunz, M.B , J. T. Harold, M B., A. M Jones, M B , D W. Liddell, M.B , R A. Moir, M B , Frances J. Pounds, M B, G. E. O Williams, M.D

Licences and Diplomas

Licences to practice were conferred upon the following 296 candidates (including 35 women) who have passed the final examination of the Conjoint Board, and have complied with the by-laws of the College:

P B. Adamson, Khairunnisa B Ahmed, W, B. Alexander, E. B. Allen, J. N H Andrews, A. H Ansari, P. Arnold, J. P. B Arthur, A. N. Ashworth, W O Attlee, A. le P. Avenell, D J. Avery, Ursula M. Bailey, W. E. S. Bain, R F. Barlow, E T Bassadone, J A Bassett, J. A. V Bates, D C P Battersea, Mary R Bayliss, R. H. Beer, J. Beeston, M. R. Beg, A. d'A Bellairs, Elisabeth I Bennett, J. Besden, J. E C. Bevan, G. A. Binns, C. A. K. Bird, N N. Blaxland, T H Blennerhassett, V Y. Bockner, Anne Bolton, W H. Bond, M M Boyle, R J. K Brown, Hilda E. Bullen, N. R Butler, J. S. Calnan, T O. Candler, P. N. Cardew, F. S Carter, A. W. H. Challis, Elinor H. Cleminson, F C Clouting, F. Cockcroft, N A Cohen, G V. Cole, J. G L. Cole, P. J. Collard, Stella M. E Cornes, J C F. Cregan, N. F. Crofts, G. H. R. Curnock, M H Dale, A J. Danby, H G Danziger, I N. Darbyshire, G. I. Davies, Audrey M Dealler, J Dean, Margot H. Dickson, E J. Wallace, A. D. J. Watt, G H. Wattley, N C. Welply, J C N Westwood, E. P Whitaker, D. A. White, E. N. Whitley, R, U Whitney, H. G. Whitworth, B F Wickham, F. R Wilde, M Wilks, D I. Williams, J I. Williams, T M. Williams, L. A. H. Willson, Anna M. T. Wilson, F. P Wimbourne, J L Withey, G Worden, G. H. Wright, H. B Wright, J K. Wright, H. J. Young, A. Zoutendyk.

Diplomas in Public Health (three), Psychological Medicine (nine), and Laryngology and Otology (five), were granted jointly with the Royal College of Surgeons of England to the successful candidates whose names were published in the report of the meeting of the Royal College of Surgeons in the *Journal* of July 25 (p. 115).

The following Diplomas were also granted, jointly with the Royal College of Surgeons:

DIPLOMA IN ANAESTHETICS.—Helen M. B. Alcock, R. E. Angel, T. H. Baillie, E. I W Barnard, J. R J Beddard, Stella G Braithwaite, T. R M Bristow, A. Coleman, Florence K Costello, J P. Cuddigan, J H. Dixon, J. D. Ebsworth, Phyllis M. Edwards, A J Evans, Mita Frost, Edith Gilchrist, G. P. Goodwin, J R. Hindmarsh, A R. Hunter, Jean E W Inglis, Edith S. M. Merry, R. E. J. Pembrey, S. F. Polley, Norah K. Priestley, H. J Richards, G. K. T. Roche, G. F Smith, A. E Ward, F Widlake, Gertrude A. Willis.

DIPLOMA IN OPHTHALMIC MEDICINE AND SURGERY —Margaret L. Clay, K. D. Foggitt, S S Freedman, D P Gurd, H E. Hobbs, M. B. Longinotto, W T C. Lumley, G O M Neatby, R L Richards, P. M. Wood.

DIPLOMA IN MEDICAL RADIOLOGY —F. H. Bonnell, G. C. D. Evans, R. C. M. Hadden, H. J. Johnson, Margaret D Snelling, J. H. Stranger.

ROYAL COLLEGE OF SURGEONS OF ENGLAND

An ordinary meeting of the Council was held on July 30 with Sir Alfred Webb-Johnson, President, in the chair. Mr. Cecil Joll was elected a member of the Surgical Section of the Board of Examiners in Dental Surgery for the year ending June 10, 1943. It was decided to continue for the duration of the war the recognition of the post of senior house-surgeon at the Devonport section of the Prince of Wales's Hospital, Plymouth, for the six months' surgical practice required of candidates for the Final Fellowship examination. It was also decided to recognize the posts of resident surgical officer and senior house-surgeon at the Royal Salop Infirmary, Shrewsbury, for the six months' surgical practice required of candidates for the Final Fellowship. Arrangements were made for the institution of a Research Chair in Ophthalmology, tenable at the College and at the Royal Eye Hospital.

Diplomas of Membership were granted, jointly with the Royal College of Physicians, to the candidates whose names appear in the report of the meeting of the Royal College of Physicians.

Diplomas in Ophthalmic Medicine and Surgery (ten) and in Medical Radiology (six) were granted, jointly with the Royal College of Physicians, to the candidates whose names appear in the report of the meeting of the Royal College of Physicians.

Blane Medal

The Gilbert Blane Medal was presented at the Royal College of Surgeons. The presentation was made by Surgeon Vice-Admiral Sir Sheldon Dudley as Medical Director-General of the Navy, in the presence of the First Lord of the Admiralty, the President of the Royal College of Physicians, and the President and Council of the Royal College of Surgeons. The recipient was Surgeon Commander Edward Rex Pascoe Williams, and the award was made to him for his original work on blast effects in warfare.

The Medal was founded in 1830 by Sir Gilbert Blane, Bt., F R.S., a distinguished physician, best known for his service under Rodney and for sanitary reforms in the Navy and for successful measures for the prevention of scurvy. It is awarded annually to a medical officer in the Royal Navy for "skill, diligence, humanity, and learning in the exercise of professional duties."

The Honorary Medal of the College has been awarded to Viscount Nuffield, G.B.E , D.C L , F.R.S., in recognition of his conspicuous service in assisting the improvement of natural knowledge and of the healing art and of his many liberal acts and distinguished labours inspired by the desire to advance the science and practice of medicine and surgery The Honorary Medal was instituted 140 years ago, and this is the 19th occasion on which it has been awarded.

ENGLISH CONJOINT BOARD

The committee of management of the Examining Board in England has decided that until further notice the examinations for the Diploma in Tropical Medicine and Hygiene (D.T.M.&H.) shall be discontinued

ROYAL COLLEGE OF SURGEONS OF EDINBURGH

At a meeting of the College, held on July 25, with Mr. J. W. Struthers, President, in the chair, the diploma of Honorary Fellowship of the College was presented to Lieut.-General Alexander Hood, C.B., C.B.E., Director-General Army Medical Services, and to Prof. Antoni Jurasz, Dean of the Polish Medical Faculty, University of Edinburgh.

The following, having passed the requisite examinations, were admitted Fellows:

G. Bankoff, H. Din, T. J. Evans, Dora J. B. Falconer, A. P. Gracie, J. D. Hallissy, A. W. Kay, G. R. Nicks, D. L. Savill, J. A. E. Watts, E. B. Wild.

CONJOINT BOARD IN SCOTLAND

The following candidates, having passed the final examination, have been admitted L.R.C.P.Ed., L.R.C.S Ed , and L.R.F.P.&S.Glasg.:

G E. Barnard, K. H. Bayatti, W. L. Bilsland, W. Brydone, B. H Budoff, R. S. David, A. R. N. Dhanji, Jess Diamond, E. S. M. Douglas, M. R. El Sarraff, A. H. Esmat, M S. A El Hamid, C. C. Haupt, El S. A. K. Himmat, P. S. Huck, C. L. Isitt, H E. Katz, I. McKechnie, R Mitchell, L. E. Mosscrop, M. A Motagalli, A. C. Muir, J. A. Murdoch, J. A. M. Ratcliffe, H. Rosenberg, A. Schmookler, M. Schneider, J. S. Seaton, S P Selvadurai, J. K. K. Stelau, B Stillerman, S. Tenzer, I. A. McL. Thomson, R. Vannithamby, Harry Walker, I. Wolff.

The following graduate of a recognized foreign university was also admitted a licentiate:

M. Gross, M D.Berlin.

The Services

NAVAL AWARD

Temp. Surg. Lieut. Gordon Paton Fahrni, R.C.N.V.R., has been awarded the D.S.C. for great bravery and devotion to duty.

EFFICIENCY DECORATION

The King has conferred the Efficiency Decoration of the Territorial Army on Lieut.-Col. (Temp. Col.) J. Rannie, R.A.M.C.

R.A.F. AWARD

The King has approved the award of the George Medal to Squadron Leader Frank George Mogg, A.A.F., and the British Empire Medal (Military Division) to Leading Aircraftman Peter Nigel Rowland, R.A.F. The citation in the *London Gazette* states:

One night in May, 1942, an aircraft crashed on the edge of an aerodrome and immediately burst into flames. Squad. Ldr. Mogg (the station medical officer), accompanied by Leading Aircraftman Rowland, hastened to the scene and found that three members of the crew had been thrown clear of the main part of the wreckage and killed; a fourth member had managed to extricate himself from the tail turret. A wireless operator was, however, trapped in the blazing fuselage, being entangled by his harness and flying clothing, which was burning. Showing complete disregard for their own safety, Squad. Ldr. Mogg, clad only in overalls over his pyjamas, and Leading Aircraftman Rowland went into the blazing wreckage to rescue the unfortunate airman. By lying flat on the floor and using a greatcoat as a shield Rowland was able to afford some protection for the medical officer whilst the latter administered morphine to the injured operator. Rowland afterwards assisted Squad. Ldr. Mogg in cutting the airman free and in extricating him from the aircraft. During the time that they were working in the wreckage two oxygen bottles exploded within a few feet of their heads, and there was grave danger that others might have done so at any time. Squad. Ldr. Mogg was badly scorched and sustained burns to his hands and wrists, but, despite this, he accompanied the dying wireless operator during the journey by ambulance to hospital some six miles away. He then fainted and had to receive medical attention. Leading Aircraftman Rowland was also burned on the hands and wrists. Both rescuers displayed gallantry of a high standard.

CASUALTIES IN THE MEDICAL SERVICES

An Admiralty Casualty List published on July 27 gave a list of the ship's complement lost in H.M.S. *Dorsetshire*, sunk by enemy action in the Bay of Biscay last April. Among them was Temp. Surg. Lieut. STANLEY WALTER PRATT, R.N.V.R., of Leighton Buzzard, who was posted as "Missing, Presumed Killed." He was educated at University College Hospital, London, and took the M.B., B.S.Lond., and the M.R.C.S., L.R.C.P. in 1936, after which he served as house-surgeon and obstetric house-surgeon at U.C.H. and house-physician at Leicester Royal Infirmary. He entered the R.N.V.R. in May, 1940, and was recorded as missing in the *Journal* of May 23 (p. 656). He was a member of the B.M.A.

Prob. Temp. Surg. Lieut. JOHN DOUGLAS JAMES, R.N.V.R., is posted as "Missing, Presumed Killed" in H.M.S. *Belmont* in an Admiralty Casualty List published on Aug. 1. He was born on July 5, 1916, qualified M.R.C.S., L.R.C.P. in 1941, and entered the R.N.V.R. as temp. surg. lieut. in Nov., 1941. His home was at Wolverhampton. He was a member of the B.M.A.

Temp. Brigadier FRANCIS GERALD AUGUSTUS SMYTH, C.B.E., R.A.M.C., died in a Middle East hospital on July 2. He was born in 1891, the youngest son of the late Col. F. A. Smyth, I.M.S., of Weymouth, and at St. Bartholomew's Hospital gained the Kirke's gold medal and scholarship in medicine, the Brackenbury medical scholarship; and the Burrows prize in pathology in 1913. He qualified M.R.C.S., L.R.C.P. in 1914 and took the M.B., B.S. degrees of the University of London in 1923. He served in France and later in India during the war of 1914-18, with a commission in the R.A.M.C., S.R. After the war he took a permanent commission as capt., was promoted major in 1926, lieut.-col. in 1937, col. in 1938, and temp. brigadier in June of this year, and had served in Egypt, India, and Palestine before the outbreak of the present war. He was appointed an O.B.E. in April, 1941, for distinguished services in the Middle East, was promoted C.B.E. in July, 1941, and was mentioned in dispatches in December, 1941. He had been a member of the B.M.A. since 1917, and in 1930 was a member of the Egyptian Branch Council.

Missing.—Capt. H. Bloom, R.A.M.C., Major J. A. G. Carmichael, R.A.M.C., Capt. H. Houghton, R.A.M.C., Capt. G. Lancaster, R.A.M.C., Capt. F. J. D. Webster, R.A.M.C.

Missing, Believed Prisoner of War.—Flying Officer J. Simpson, R.A.F.V.R.

Prisoners of War.—War Subs. Capt. W. G. H. Allen, Lieut J. W. Anderson, R.A.M.C., Temp Major J. D. Fraser, Temp. Major J. D. A. Gray, R.A.M.C., Major G. F. Harrison, Capt. A. F. Hutchison, R.A.M.C., War Subs. Capt. J. A. MacLeod, R.A.M.C., Temp. Surg. Lieut. R. St. C. Mooney, R.N.V.R., Major J. H. Prain, Temp. Major O. G. Prosser, R.A.M.C., Lieut.-Col. J. K. Steel, R.A.M.C., Capt. J. A. Sutherland, R.A.M.C., War Subs. Capt. A. C. P. D. Thomson, R.A.M.C.

The announcement concerning Surg. Lieut.-Cmdr. Walter Gordon Gill, R.N.V.R. (mention in dispatches), published in our issue of January 24, p. 132, should have read Surg. Lieut.-Cmdr. William Gordon Gill, R.N.V.R.

Medical Notes in Parliament

House of Lords Debate on Tuberculosis

In the House of Lords on July 28 Lord DAVIES drew attention to the failure of the Ministry of Health to deal with the staffing requirements of institutions for the treatment of tuberculosis. He appealed to the Minister to take every step he could to increase the facilities for treatment of tuberculous patients and to use the accommodation in the emergency hospitals until the beds there were required owing to the war. The Earl of HUNTINGDON deplored the tremendous depletion in the number of doctors available for civilians. Some way ought to be found whereby the War Office could arrange for the big and almost immobilized reserve of doctors in the Forces to go out and take evening surgeries, and so help the immensely overworked general practitioner.

Viscount DAWSON OF PENN said that although we were concerned with the increase in tuberculosis in this war, we should keep a sense of proportion. A more anxious feature was the selective character of the infection among different classes. In this war, as in the last, there was a tendency for increase of infection in young women. The most notable characteristic of tuberculosis in this war so far had been an extension of the infection among young children. It was particularly noticeable in the higher incidence of tuberculous meningitis, from which there had been increased mortality amounting to 50%. The cause of tuberculosis in war was, broadly speaking, a combination of more opportunities for infection and decreased resistance. It was true to say that, on the whole, the disease was under control, and there was no sign that it was running away with us, although the total rise of mortality in Great Britain during the war, which was 13%, was a considerable figure. Tuberculosis was a germ disease which did not come in waves on us; it was always with us; its root was in almost every country.

The Problems of Infection

To grasp the problems of infection, Lord Dawson asked the House to consider in what way people contracted tuberculosis. There were three ways: one was by contact with the expectoration of a case of established disease; a second was by the reawakening of the disease in someone who had had tuberculosis and recovered from it; and the third, because tuberculosis was conveyed by drinking the milk of a tuberculous dairy cow. In a country like this, where a large proportion of the cattle were tuberculous, it would be a wise precaution to pasteurize the milk. Pasteurization was patchy; it was extremely good in London, good in some boroughs and bad in others, while in the country districts more of the milk drunk was raw. While children were in London they drank pasteurized milk, but since they had been evacuated to the country they had drunk raw milk. Investigation was going on to confirm or refute what he was going to say, but it was not unreasonable to suppose that the increase in tuberculosis in children might be accounted for partly by the fact that they had passed from drinking pasteurized to drinking raw milk

Towards Mass Radiography

Referring to lung tuberculosis, Lord Dawson said that here infection was invariably brought about by contact with the expectoration of an established case, and it was obvious that under the overcrowded conditions of wartime, with the lack of ventilation and other difficulties, the opportunities for contracting tuberculosis must be greater than in peacetime. The question was, how to reduce the trouble to a minimum. The chief difficulty lay in the fact that it was quite common for an infected person in a factory or a home to have symptoms so vague that it was not realized that he was an infected person. Progress was being made in the establishment of mass radiography. We were not dependent solely on the U.S.; there were machines in this country which had been standardized according to an agreed pattern, and which would be turned out in increasing numbers from now onwards. The machine had the advantage that in skilled hands—he emphasized those words—as many as 3,000 examinations a week were possible, and it was possible to organize the examination of a whole factory in a very short space of time. He thought this could be done far better by persuasion than by compulsion. There were good grounds for supposing that mass radiography would be received with increasing favour as the people concerned understood it. That would lead to the discovery of early cases, which were difficult to find by other means. We had to be careful not to speak too optimistically about new inventions. Mass radiography was going to be a great aid, but it had to grow into our system of medicine discreetly. To dispatch large numbers of machines all over the country without proper teams to work them would make a very bad beginning and lead to false conclusions. He had reason to think that the Ministry and the medical services of the armed Forces were aware of that. It was easy to see that if we could remove one infected person from a part of a factory which might contain a hundred people, or take one infected person away from his home at an early stage, we might do much towards reducing the incidence of this disease.

Education without Alarm

On the question raised by Lord HUNTINGDON about the depletion of doctors, Lord DAWSON said there had been no more depletion than was really necessary. The Army, where it could, gave facilities for medical officers in military depots to give a hand. Referring to the education of the public by the cinema, he said he was doubtful of this. A difficulty in all matters concerning health was to give information without producing alarm, and one of the things we had to be careful about in mass radiography was not to raise a sense of alarm among the workers. The danger was that they would swing from indifference to over-anxiety, and he would rather have indifference than over-anxiety in the case of illness. He thought that mass radiography, so far as we had watched it up to the present, had been well received, and if it was presented to the people as it should be presented, as a means of establishing how well people were and not how ill they were, it could be useful. It should be made part of a health measure, which was one of the features of the Youth Movement to-day, as contrasted with health propaganda which made a self-conscious people.

Speaking on rehabilitation Lord Dawson said we must realize that in tuberculosis there must always be a long period between the end of sanatorium treatment and full-time work. He thought that the Ministry of Health were fully alive to this, and that they proposed to consider seriously the maintenance and subsidizing of tuberculosis subjects for a period from the time they left the sanatorium to the time when they got back to work—if they were on a half-time basis, to make up their wages for so many weeks or months. As regards nurses, if it was made clear that there was no more risk of a nurse getting tuberculosis in a sanatorium than in the ordinary ward of a hospital, in fact, rather less if anything, and if in some way the care of the tuberculous patient could be made part of a nurse's duties—she might, for example, be seconded from medical and surgical wards to tuberculosis wards—the difficulty could to a large extent be got over. Of one thing he was sure, and that was that to start any process of compulsion, to make a nurse take up a particular phase of nursing, would end in failure. If an adequate appeal were made, and tuberculosis were made part of the general care of the sick, he thought that the difficulty about nurses would disappear.

Government Answer: Staff Difficulties

Lord SNELL, replying to the debate, said that Lord Dawson had traversed much of the ground which he himself would have covered. It was of considerable importance to have his judgment that, serious though tuberculosis was, it was not incurable and was not a matter either for a grave view or for despair in regard to its treatment. The difficulty was not one of accommodation ultimately, but of staffing facilities. The lack of an adequate staff in the nursing service was not confined to institutions that had to deal with the treatment of tuberculosis. In sanatoria, for which the Ministry received a periodical return of the available nursing and domestic staff, roughly, 4,800 domestics were employed and 920 more were needed. The position, unsatisfactory as it was, was slightly better than a year ago. In 1941 the deficiency was 17%; in 1942, so far as the figures showed, it was 16%. The need was recognized by the Government, and women domestics in these establishments were reserved. The Ministry of Labour had also instructed regional controllers to give high preference to these needs.

An increase in the total number of nurses was being secured. There were 2,000 employed in tuberculosis sanatoria, and it was estimated that 600 more were required and another 600 for beds in other hospitals for tuberculosis. Therefore we needed an immediate enrolment of about 1,200 nurses. The fear of contracting infection was no doubt one factor which had created a prejudice in the minds of girls and even of their parents, but the Minister had made it clear that nursing in a sanatorium need involve no greater risk of contracting tuberculosis than nursing in other hospitals. He was gratified that Lord Dawson had spoken against compulsion in the service. The Department did not think that compulsion ought to be necessary, but they might have to consider a wiser exercise of their powers of direction. A substantial number of student nurses under 21 were employed on the permanent staff of sanatoria, and every care was taken to prevent them from becoming infected. The Ministry were now proposing to modify the embargo, that nursing auxiliaries of the reserve should not be allocated to sanatoria even if they volunteered, by allowing nursing auxiliaries under 21 to serve in sanatoria if they volunteered, provided, of course, that the fullest precautions were observed in looking after their health.

In Defence of Doctors

Lord Snell admitted that ground had been lost between 1938 and 1941 with regard to the number of deaths from tuberculosis. The stripping of the population of their ordinary doctors might or might not account for some of the increase, but he had never felt able to join in gibes at the medical profession. He had felt it right to defer criticism of their work until they had been provided with social conditions such as were required to make that work effective. We could all criticize the doctors when we were well and they were none the worse for the criticism, but we should remember that they had to work under conditions unsuitable for their work. We ought also to remember that if the national health had improved, as it had, it was probably because we were all of us compelled to do now what the doctors had always told us we ought to do.

The ground lost had been due, he thought, to war conditions, which the doctors and the Ministry of Health could not control. The ways of recovery were known and would be open to us to adopt as soon as the war ended. There would be the possibility of earlier diagnosis. It had been difficult to get the necessary equipment of late, but British-made instruments were becoming available and teams of trained workers would be ready to undertake this work by the end of this year.

Glasgow Small-pox Outbreak

On July 28 Mr. JOHNSTON, replying to Mr. A. Edwards, said that the ages of the small-pox patients removed to hospital in Glasgow during the recent outbreak were: (*a*) 10 cases from the ships aged 17, 19, 20, 21, 22, 23 (four), and 28 years, respectively; (*b*) 29 civilian cases aged 3, 5, 6, 7, 8, 11, 12, 13 (two), 14, 15, 16, 20 (two), 22 (two), 29, 31, 34, 35, 37, 38, 40 (two), 49, 56, 65, 67, and 72 years respectively; and (*c*) 6 fatal cases (included in the foregoing) aged 20, 25, 28, 38, 65, and 72 years respectively. Of the 10 cases from the ship only one was vaccinated before May 29, a passenger, aged 23, who had been vaccinated at 1, 7, and 14 years; all except the original case were vaccinated on May 29 and two were revaccinated on June 10 and 11 respectively, the first vaccination having been unsuccessful.

Medical News

The War Office announces that Col. A. B. Austin has been selected for appointment as Director, Army Dental Service, in succession to Major-General D. Clewer, C.B., whose tenure expires on August 31.

A meeting of the main executive committee of the Medical Superintendents' Society will be held at the Midland Station Hotel, Leicester, to-day (Saturday, August 15) at 2.15 p.m. It may be necessary to continue on Sunday, August 16.

Schemes for the co-ordination of hospital activities are reported from many quarters in these days of medical planning, and the King Edward's Hospital Fund for London, which held its annual meeting in London recently, has, in conjunction with the Voluntary Hospitals Committee, set up a joint committee on co-ordination under the chairmanship of Lord Donoughmore. The Duke of Kent, who announced this in his Chairman's address, said that the Fund was also assisting in the Ministry of Health's survey of hospital facilities in London and the Home Counties. At the invitation of the Fund the chairmen of the London teaching hospitals had met and set up a committee of their own in connexion with the Government's inquiry into the organization of medical schools and the facilities for clinical teaching and research. Some co-ordination had already been achieved in London For example, there was the Nurses Recruitment Centre of the Fund, through which many hospitals were now obtaining a large proportion of their student nurses. Then there was the Contributory Schemes Committee, established a year ago, which aimed at encouraging only one such scheme for the London region. The treasurer of the Fund announced at the meeting that the total distributed during the year had been, with expenses and special services, £313,000, or £44,000 more than the net receipts, which meant they would have to draw on reserves. Subscriptions, donations, and income from investments were all less than in 1940, but the position as regards legacies for 1942 was better than in 1941, so the outlook for the Fund's finances in this respect was promising.

Dr. G. E. Friend, medical officer to Christ's Hospital, Horsham, has accepted the invitation of the members of the Food Education Society to become its honorary general secretary.

EPIDEMIOLOGICAL NOTES

Discussion of Table

During the week under review large rises in the notifications of measles occurred in Kent, 78, and Nottinghamshire, 55 (108 of the 192 cases were recorded in Nottingham C.B.). The largest decreases were those of Lancashire, 213; Essex, 74; Middlesex, 65; and London, 52.

Diphtheria was more prevalent in the North than in the South. The Counties of Lancashire, Yorks West Riding, and Durham contributed 282 cases out of the total of 710 for the whole country.

Only 3 further cases were reported from the outbreak of dysentery in Derbyshire, and 7 from Cumberland, Penrith U.D., where nearly 200 cases of Sonne dysentery due to infected milk have been reported.

In London 24 cases of dysentery, almost one-quarter of the total, were notified. The only local outbreaks of any size were those of the cities of Oxford, 11 cases, and Birmingham, 8.

The incidence of paratyphoid and typhoid fevers has been at a very low level during the present year. Only 176 cases have been recorded in the large towns, compared with 1,268 cases in the corresponding period of last year. Although the incidence has fallen the case fatality has risen; the ratio of deaths to cases has been 1 to 7, compared with 1 to 30 in the same period of last year.

In Scotland the chief features of the returns were a decrease in measles, 32 cases, and an increase in the notifications of acute primary pneumonia, 24 cases. These fluctuations were due to the experience of Glasgow, where measles fell by 34 cases and pneumonia rose by 31.

Small-pox

One further case of small-pox was reported in Glasgow, at the beginning of the month, from an institution where a previous case had occurred. At the beginning of August there were 16 cases of small-pox in hospital in Glasgow and only one in Swindon. Many of the suspected cases have proved to be of chicken-pox.

Returns for the Week Ending August 1

The notifications of infectious diseases in England and Wales during the week included the following: scarlet fever 1,456, whooping-cough 1,116, diphtheria 650, measles 6,476, acute pneumonia 418, cerebrospinal fever 69, dysentery 64, paratyphoid 6, typhoid 9.

No. 29

INFECTIOUS DISEASES AND VITAL STATISTICS

We print below a summary of Infectious Diseases and Vital Statistics in the British Isles during the week ended July 25:

Figures of Principal Notifiable Diseases for the week and those for the corresponding week last year, for: (a) England and Wales (London included). (b) London (administrative county). (c) Scotland. (d) Eire. (e) Northern Ireland.

Figures of Births and Deaths, and of Deaths recorded under each infectious disease, are for: (a) The 126 great towns in England and Wales (including London). (b) London (administrative county). (c) The 16 principal towns in Scotland. (d) The 13 principal towns in Eire. (e) The 10 principal towns in Northern Ireland.

A dash — denotes no cases; a blank space denotes disease not notifiable or no return available.

Disease	1942					1941 (Corresponding Week)

* Includes primary form for England and Wales, London (administrative county), and Northern Ireland.

† Owing to evacuation schemes and other movements of population, birth and death rates for Northern Ireland are no longer available.

Letters, Notes, and Answers

All communications in regard to editorial business should be addressed to The EDITOR, British Medical Journal, B.M.A. House, Tavistock Square, London, W.C.1.

ORIGINAL ARTICLES AND LETTERS forwarded for publication are understood to be offered to the *British Medical Journal* alone unless the contrary be stated.

Authors desiring REPRINTS should communicate with the Secretary of the Journal Board, B.M.A. House, Tavistock Square, W C.1, on receipt of proofs. Authors over-seas should indicate on MSS if reprints are required, as proofs are not sent abroad.

ADVERTISEMENTS should be addressed to the Advertisement Manager (hours 9 a.m. to 5 p.m.). Orders for copies of the *Journal* and subscriptions should be sent to the Secretary.

Telephone No.—B.M.A. and *B.M.J.*: EUSTON 2111.

Telegraphic Addresses.—EDITOR, *Aitiology Westcent, London*; SECRETARY, *Medisecra Westcent, London.*

B.M.A. Scottish Office: 7, Drumsheugh Gardens, Edinburgh.

QUERIES AND ANSWERS

Itching of Limbs

Dr. W. A. Milligan (London, W.1) writes: I have a patient, male, aged 79, who for the last two years has suffered from intolerable itching of the skin, more especially round the ankles, thighs, and arms. No rash of any kind, except the marks from scratching. All the irritation goes completely whenever he puts on his clothes in the morning, and does not trouble him again till he takes off his clothes at night. All the ordinary remedies have been tried, with no effect. His organs are all quite healthy, except for a slight prostatic enlargement. Can anyone suggest a treatment?

Artificial Respiration in Phosgene Poisoning ?

Dr. F C. Eve (Hull) writes in reply to Dr. J. L. Barford who asks (Aug. 1, p. 148) for information about the above question, on which opinions differ: In 1938, I gave a lecture in London on "gravitational nursing" in which various uses of my tiltable bed were demonstrated. It can be tilted (and clamped) around a central axis at any desired angle, head up or head down. When the clamps are removed the bed can be used to produce artificial respiration efficiently by Eve's rocking method (a dozen double rocks a minute through a total range of about 60° shifts the diaphragm up and down by gravity: see *Lancet*, March 11, 1939) At the lecture a colonel in the R.A.M.C., who had experience of "choking" gases in the last war, was in the chair. He felt confident that the steep head-down tilt available in this bed would be very valuable in cases drowning in their own secretions from gas poisoning. He sent the manufacturer to the War Office with a note to that effect. Later, a number of these beds were ordered by the Ordnance Dept. and also by the Air Ministry. Although I cannot speak from experience of irritant gas poisoning, my original case of a child drowning in her own secretions (from post-diphtheritic paralysis of the diaphragm) was quickly relieved of her "death-rattle" by a steep head-down tilt and then permanently cured by two days of artificial respiration by rocking. Hence the tiltable bed should certainly relieve cases of gas poisoning in the "drowning" stage by the drainage (? intermittent) of a steep head-down tilt (bed-blocks inadequate). Artificial respiration by rocking could then be proceeded with on the same bed—if and when it gave relief. (The manufacturers are Sidhall & Hilton, Sowerby Bridge, Yorkshire; the price is, or was, very moderate.) The pelvis (not the chest) may be immobilized on the bed by a cross-over girdle extemporized from a motor-car inner tube with 2 cords pulling it upwards and 1 (median) pulling it downwards. These distressed patients would presumably not tolerate Schäfer's method but might stand the rocking method (on and off), which is equally efficient and should aid their respiratory efforts it synchronized with them.

Income Tax

Expenses of Assistant

O. G. is an assistant living away from his principal's premises. Messages are delivered at his residence, and he sees patients there. What proportion of the cost of his rent, heating, lighting, domestic services, etc., can he claim?

⁂ It is assumed that the professional use of his residence is one of the conditions—express or implied—of his assistantship, otherwise he has no legal claim for any allowance. As regards any proportion, it is impossible to offer any suggestion without full details of the total accommodation, etc., and the extent of professional use. The test is what is reasonable in the circumstances of each case, and O. G. may find that the best way of arriving at a settlement is to call on the inspector of taxes, explain the position, and endeavour to agree a reasonable figure.

LETTERS, NOTES, ETC.

Warmth in Winter

G. D. G. writes: The coming winter hardships of fuel shortage would be greatly mitigated if we were to follow the methods of Northern Chinese who pass through five months of rigorously cold weather, with low fuel consumption, in comparative comfort. They have a simple rule—the colder the climate the more clothes they wear. A wadded gown with long sleeves and wadded trousers bound round the ankle make them independent of a chilly room. Men, women, and children of all classes wear these wadded (cotton-waste) garments. In North China they would laugh at the spectacle one sees in this country of our womenfolk clad in thin "undies" with short skirts and silk stockings shivering with cold. Also, the Chinese do not have the open fireplaces we have with 70% of the heat going up the chimney: they install a small stove in the far corner of the room and lead a long chimney metal pipe right across it The bigger the room the longer the pipe. This radiates heat from a few pounds of coal in a slow-burning simple stove

Blood Serum in Local Treatment of Burns

Dr. F. W. Simpson (Perth, W. Australia) writes: For some time now I have been using blood serum for the local treatment of burns and wounds of any nature. The burns are cleansed in the usual manner, the loose skin being removed, and serum applied by means of a pipette. This is repeated every hour for 12 hours to tampons applied to the burnt area. In fact the serum simply takes the place of tannic acid in the usual treatment of burns. If the burns are extensive, mixed blood serum is also given intravenously. I think the serum is the ideal dressing for burns of the hand and face, as it is a simple supplement of Nature's own exudation of serum to the raw areas. The results have been excellent. I prepare the serum myself by drawing it off from blood after standing for a few hours. The serum keeps for a month or so if stored in a refrigerator.

Silver Nitrate in Excessive Bleeding

Dr. G E. H. Le Fanu (Liverpool) writes: The interesting case of death in a haemophiliac after tooth extraction reported by Messrs Endicott, Mitchell, and Qvist (July 11, p. 34) has brought to my mind two cases of oozing after tooth extraction in middle-aged women: one had been bleeding for 15 hours, the other for 24. In both cases arrest of bleeding was immediate after insertion between finger and thumb of a stick of silver nitrate into the cavity and gentle rotation from side to side for a few seconds; bleeding did not recur and healing was uneventful. I have never seen any reference to this method: it should be worth trying.

MEDICINE 100 YEARS AGO

Extract from the *Provincial Medical Journal* for August 13, 1842, being a letter to the Editors under the heading "Professional Etiquette":

"Gentlemen,—In justice to the profession to which I belong, I lay the following glaring case before the public. Had it been a single instance from the same quarter, I might not have noticed it; but as it is only one out of many, equally bad, I select it as of most interest.—I remain, Gentlemen, yours obediently,

William Reeves,

Carlisle, August 8, 1842 Surgeon to the Carlisle Dispensary

"A young man, a dispensary patient under my charge, laboured under stone in the bladder, for which I advised him to submit to an operation. I stated to him that I would perform the operation in his own house, or, if he preferred it, he might go to the infirmary, where more conveniences would be provided than he could otherwise have. This, the young man said, he would decide upon in a short time. However, in the meantime, the apprentice to a general practitioner in this town, Mr. Elliot, met the young man in a joiner's shop, on leaving which the patient said, 'I must go and see Mr Reeves at the dispensary' The apprentice asked what ailed him, and the patient answered, 'I have got a stone in the bladder.' The apprentice then advised him to call upon Mr. Elliot, and the lad did so. After the patient had answered Mr. Elliot's questions, and stated that Mr. Reeves had advised him to submit to an operation, Mr. Elliot intimated that if he allowed himself to be operated on he would surely die, and at the same time read to him some statistical table, showing that almost every one died after an operation for stone. Mr. Elliot then proceeded to examine him—stated that there were two stones, and that he could cure him without cutting, or any danger. This the man gladly listened to, and came and told me what I have above stated. I told him I never discovered more than one stone, and if Mr. Elliot had persuaded him to the contrary, he would ultimately find out his mistake. At the same time, I told him that no operation could be unattended with danger. After a short time Mr. Elliot operated, cut down upon the membranous portion of the urethra, dilated the prostate, and took away one small stone."

LATE REHABILITATION OF THE INJURED

A SURVEY OF SEVEN YEARS' EXPERIENCE IN AN INDUSTRIAL CLINIC

BY

ALEXANDER MILLER, M.B., F.R.C.S.Ed.

Regional Consultant Orthopaedic Surgeon, E.M.S., Scotland, and Lanarkshire Orthopaedic Association,
Senior Assistant Surgeon, Fracture Department, Victoria Infirmary, Glasgow

Informed opinion is agreed that rehabilitation of the injured is inseparable from early treatment of the original trauma, and the importance of this was adequately stressed in the Delevingne Report of 1936 (*British Medical Journal,* 1937, **1**, 1218 ; 1939, **2**, 417, 461). Since time must elapse, however, before the changes recommended in such a report are generally accepted, some measure of compromise is necessary to encourage further progress, and the work of the Lanarkshire Orthopaedic Association is an attempt to improve some of the existing anomalies. The following report is a survey in narrative of the work of this association to date.

Before the present war, regional hospital service in Scotland had not developed to the same extent as in England, and thus it happened that the large industrial county of Lanarkshire, where coal-mining constitutes a major source of employment, depended mainly on Glasgow for all hospital and out-patient treatment. Trauma is a common occurrence in the mining industry, and as a result of this there were accumulating an increasing number of patients who had recovered in part from their original trauma but who were still scarcely well enough to return to their previous occupation. This raised among medical practitioners the question of providing a centre in the county where provision might be made for further treatment of these cases.

Following on a number of preliminary meetings with representatives of all those interested in the problem, an Orthopaedic Association was formed in 1935 with an Executive Committee consisting of six members of the body known as the Lanarkshire Medical Practitioners' Union, three members of the Coalmasters' Association, and three members of the Mineworkers' Union. It was agreed that maintenance costs should be borne equally by the mineworkers and coalmasters, and that a grant towards equipment should be made by the Miners' Welfare Committee. The problem of travelling expenses for patients attending the clinic necessarily arose, and this difficulty was overcome by the coalmasters making a grant to cover these.

The first session of the clinic was held in May, 1935, at Motherwell, a central town providing easy access by rail and road from all the surrounding mining areas. Accommodation was provided in the out-patient premises of the County Fever Hospital, whose *x*-ray facilities were placed at the service of the clinic. In the course of the first two years three further treatment centres were opened in welfare institutes adjacent to the main industrial centres.

The Ideal Aimed At.—At the beginning of the experiment it was stressed that the objective was the segregation of all injured employees at the earliest possible time. Unity of control throughout the period of treatment, and until full working capacity or maximum improvement was obtained, was highly desirable; but, since hospital facilities were not at present available locally, it was indicated that an attempt would be made to deal with that group of patients comprising the late stages of trauma.

Staff and Equipment

An orthopaedic surgeon controls the activities of the clinic and has the right to refuse treatment where this is unlikely to further the progress of the patient. In a clinic of this nature such a mandate is important, as otherwise patients who are out of work might be apt to look on the clinic as a club centre and thus falsify statistics, or at least give an untrue picture of the position. Treatment is carried out by an orthopaedic sister who is also a qualified masseuse. During the past year a secretary and a liaison officer have been added to the staff. The duties of the liaison officer are referred to later.

On the surgeon's recommendation it was originally decided to equip the clinic with simple radiant-heat baths and to add apparatus as circumstances demanded. The wisdom of this decision has been amply demonstrated in practice, for, apart from a heavy rowing-machine and plinths, all other apparatus has been devised from simple ropes, pulleys, and sandbags. In treating this type of patient the essential requirement is a well-trained orthopaedic sister, with personality and patience rather than an academic knowledge of electro-magnetism.

Working of the Clinic

There was some antagonism to the scheme in its early months, for the workman tended to view it as an attempt to coerce him to return to his labour, and the surgeon was apt to appear to him as an ally of the compensation authorities. At first there were many prolonged and heated arguments related to these points, but gradually the clinic came to be accepted purely as a treatment centre which had no aim beyond that of aiding and perhaps accelerating the return of the patient to full physical well-being. Two principles have been adhered to throughout and have helped to win the confidence of the patient. First, the surgeon's record cards are private, and the only progress notes sent out are dispatched direct to the patient's own doctor. Secondly, no medical reports are made by the surgeon on behalf of either patient or employer. This I believe to be an indispensable rule in the working of this type of clinic; otherwise, the possible appearance in the law courts of the surgeon in charge tends to create a suspicion of bias and invalidates the usefulness of the clinic as a purely therapeutic centre. Personal experience has shown that this has encouraged the patients to be frank in stating their views, their fears, and their grievances, so that they often seek advice before coming to a decision in respect of the particular difficulties of their problem. From this factor has emerged a social aspect to the problem of those injured in industry which, in the view of many of those concerned, is being inadequately dealt with.

Type of Patient

It is unusual to see a patient who has not been under treatment elsewhere for some time. The period varies in the case of a soft-tissue injury from a few days to six months, and in the case of a fracture from months to years. In most instances no notes of previous treatment accompany the patient, and previous records are often difficult to obtain and frequently incomplete. A considerable number of patients not inaptly illustrate the expression "broken men."

The great proportion of patients are in receipt of compensation, although some are receiving national health insurance benefit. In the past two years there has been an increase in the number of patients seeking treatment while still attending their work, and there has been a tendency to refer minor injuries at an earlier date, but, on the whole, the bulk of the patients conform to the comprehensive title suggested above.

In the early months of the clinic's activity attempts were made to tackle the problem of providing "light work" in the mining industry, and in 1937 the Executive Committee finally agreed to a formula of occupational therapy in the form of "alternative work." The mineworkers stipulated that this work should not include such duties as those at present performed by the aged or by young boys, but should consist of some alternative duty specially provided. Agreement was reached by deciding "that in any instance where the surgeon considered that the patient would benefit from alternative work, then suitable duties should be provided at the rate of 25s. per week in addition to patient's compensation allowance, based on the earning capacity of 25s. per week." It was made a condition that this should not prejudice the patient if any later disagreement occurred regarding his physical fitness and where an appeal was made to the medical referee.

In practice this scheme was difficult to administer, as its hope of success lay in the full co-operation of everyone concerned, and it became clear that the presence of a liaison officer, to act as an intermediary in the home and at the pit-head, was necessary.

Social Service and the Liaison Officer

Experience of the valuable work which a trained almoner was accomplishing in an orthopaedic and fracture clinic to which I am attached pointed the way to a solution of many problems. As the patient gained confidence in the clinic workers he occasionally revealed problems of his private life which were greatly aggravating his physical burdens, and the advantages to be gained from the services of a trained almoner were placed before the committee. The suggestion of such an appointment did not meet with whole-hearted approval, the main opposition coming from the miners' representatives, who feared that such an arrangement would interfere with the liberty of the men and the privacy of their homes. In 1940, however, it was agreed to allow a trained almoner to work under the direction of the surgeon for a probationary period of six months. Her duties consisted in visiting the home of each patient, where her help in solving domestic burdens in cases of family illness, in arranging holiday convalescence, and in obtaining suitable training for younger members of the family earned general gratitude.

Contact was made with the unemployment bureau, with the industrial firms in the county, and more particularly with the various colliery managers. This personal approach has done a great deal to enlist sympathy and help. In the colliery, special work was arranged for 14 recommended cases in the first few months. Graduated duties were also arranged for many patients so that they might accustom themselves to the routine of their previous work. Similarly, where wet workings were often responsible for broken time in cases of the "rheumatic diathesis," arrangements were made to give recommended cases more favourable working conditions. In the past year 87 employees have benefited by this arrangement. Many relatively trivial matters were also dealt with, and the action taken has promoted a better mutual understanding of real or apparent grievances.

Recently, the emergence of the Government Training Scheme has opened up a wide field of possibilities for dealing with many of the problems of late rehabilitation, but the personal approach of the liaison officer to industrial concerns in the county has up till now yielded more immediate results.

Clinical Conditions

The complaint is usually one of pain, swelling, deformity, or stiffness related to the limbs or trunk. The proportion of soft-tissue injuries is greater than that of fractures, and by the time the patients are first seen healing of bone is almost invariably established.

Recently a card index has been prepared so that a more accurate statistical record may be made, but this is only due to be brought into operation now. It is based on the punch record system. The back of the card is reserved for treatment and progress notes.

Trauma and Arthritis.—In injuries affecting the muscle–joint system signs of arthritis are often detected clinically and radiologically, especially in the knee, hip, and spine. Radiological evidence of arthritis is very uncommon in the shoulder-joint proper even where clinical evidence is unmistakable, but irregularity of the acromio-clavicular joint is not unusual. Indications of arthritic change in other parts of the muscle–joint system are the rule even although these have remained symptomless to date. During routine examination clinical evidence of arthritis is sometimes detected in relatively young miners without any previous disability having occurred, and it is clear that this factor will predispose to joint injury and incapacity. The working conditions of cramped posture, damp, and repeated minimal traumata are all accepted factors predisposing to osteo-arthritis, and this relation of trauma to arthritis is an ever-present one in the mining industry. Spinal injuries due to twist or strain are notoriously common, and here again underlying arthritic changes which have been present over years of work in the mines are usually evident. The superimposed trauma is literally the "last straw," and the result is prolonged incapacity.

Age.—Tissues show the usual evidence of wear and tear from arduous work in the mines, but age in actual years plays little part in deciding working conditions for the individual. Not infrequently men between 60 and 70 are still actively engaged in work at the coal face, and although it is obvious that they are becoming more liable to injury it often requires some "accident" to bring about their retirement from labour Frequently we see youths and young adults who are quite unsuitable for working conditions below ground and who are heading for early invalidism unless transferred to more suitable surroundings. Their attendance at the clinic is due to their working at a strain quite beyond their physical capacity.

Mental Attitude.—As a group the mining community is not nervous, though a few individuals have had their confidence shaken by imprisonment under falls from the roof and will not be fit for duty again if this necessitates return to their previous environs. On the whole they accept the discomforts of work with little complaint, but when faced with injury are unyielding in their demands for retribution. They are keen on any hazard, and thus are tempted to gamble with the "lump sum" settlement. Their generosity to an injured colleague is common knowledge: we had a recent example of this when a group on pay-day subscribed enough to purchase the "best artificial limb" for a disabled colleague rather than delay until "Charitable Boards" came to a decision.

Treatment

Experience at this clinic has shown the importance of the social aspect of rehabilitation of those injured in industry, and in my opinion it should form an integral part of any comprehensive scheme. A change of environment was desirable in many of the patients examined, and this was arranged by encouraging a greater use of the facilities existing in the Miners' Convalescent Home. It entailed a break in continuity of treatment at the clinic; but the patients were never away for longer periods than 7 to 14 days, and the occasion was thus used in the nature of a complete change from home and treatment. In 1938, however, the advantage of a residential rehabilitation centre in country surroundings was advocated as a reason for further extension of the scheme, and the committee still had this matter under consideration when war supervened. At present the difficulty is being partly overcome by utilizing accommodation in an E.M.S. country hospital where the facilities of an orthopaedic service are available under the same surgical supervision as the clinic.

Only the principles of treatment will be mentioned here, as routine exercises vary little in nature from those described in recent articles on rehabilitation by Watson-Jones, Nicoll, and others. Most of the patients have local heat applied to the affected part, and a simple radiant-heat bath has proved adequate for this purpose in practically all cases. Active exercises are carried out on a graduated scale, and resistance exercises are begun as soon as muscle power justifies this. Recourse to passive stretching is seldom made, and then only under surgical guidance, but manipulation under general anaesthetic is occasionally required. In such instances the patient is transferred to hospital for at least a 48-hour period to ensure immediate post-manipulation co-operation in exercises. Electrical stimulation of an atrophied muscle is rarely practised after voluntary contraction is obtained, greater reliance being placed in the re-educational skill of the orthopaedic sister than in the effects of electrical stimulation.

Each patient is taken individually until he understands his instructions, and thereafter he is transferred to a class in which the competitive spirit is encouraged. The introduction of exercises to music was a popular innovation, and is now routine in all class exercises. At a later stage in treatment, when the patient is approaching fitness for work, he is encouraged to use the implements of his trade, but these have no place in the early stages of treatment. It is important that working posture be fully appreciated in any scheme of treatment, and in order that this might be understood and applied, the staff have visited the coal-mines and noted the attitudes adopted for each branch of the work. This knowledge has also proved of benefit when giving advice regarding suitable graduated duties before a patient returns to his previous work.

Some patients need local splintage as a temporary measure to support weak muscles during their stage of recovery. Others, again, require a more permanent type of support to aid function, as in drop-foot, or to control painful movements of a joint in the presence of gross arthritis.

As previously stated, the greater part of the equipment used in the clinic is devised by the orthopaedic sister from simple ropes, weights, and pulleys.

Some Unusual Anomalies

Compensation

Case 1.—A patient, after a crush injury at work, was left with spastic paralysis of lower limbs and permanent incontinence of bowel and bladder. He was first seen at the clinic following on two years' recumbency treatment, and after instruction was finally able to walk by the aid of spinal brace, callipers, and stick support. To relieve the monotony of existence he opened a small shop in his own home, but was advised that any attempt on his part to serve behind the counter would result in his compensation being reduced to that of partial incapacity.

Case 2.—Following on compound fracture of a lower limb with resultant knee and ankle stiffness the patient's general condition improved and he was advised to do home gardening to accustom himself to shovelling, etc. He was agreeable, but reported later to say he was informed that this would result in his being classified as fit for light work. Though this was possibly true, it delayed purposeful re-educational exercise in a willing patient.

Legal

Case 3.—A patient who had almost fully recovered from his injury was advised to consider return to graduated duties when reporting to his compensation board in a few days' time. He seemed troubled regarding this suggestion, and explained that he was under legal advice. It transpired in subsequent discussion that his law agent lived some 80 miles away, that he had never seen his agent, and that his case had been booked by a colleague who acted as a tout on a commission basis.

Trade Union

Case 4.—A patient under 18 years of age lost his leg as a result of an accident at his work and showed a desire to take an alternative vocational training. Arrangements were made for his absorption into selected secretarial work, but he was counselled by his union to delay settlement until his claim could be considered on an adult basis, it being stated that if he sought training prior to settlement it would prejudice his case. This introduced the psychological problem of possible change in mental attitude of a young patient during a long period of inactivity and a probable lost opportunity of training. The patient's guardian agreed to accept the personal responsibility of settlement and immediate training.

Results

It has been difficult to keep a close and accurate follow-up of all cases discharged from treatment since the clinic started, but this has been rendered easier since the appointment of the liaison officer, and it is hoped it will be less laborious with the new index system of records. In the earlier years, statistics were maintained by reports from new patients concerning the activities of previous patients known to them either through domestic or working contacts—the freemasonry of the miner—or by direct communication. The results are shown in the Table.

Annual Report	No of Patients Examined	Cases Unsuitable for Treatment	Cases Returned to Full Duty or Settled and Working
1935–6	183	20	123 (75%)
1936–7	221	14	136 (65%)
1937–8	325	25	208 (69%)
1938–9	378	36	270 (78%)
1939–40	350	18	229 (68%)
1940–1	414	19	303 (76%)
1941–2	385	37	274 (78%)

Conclusions

Early treatment of traumatic cases under unity of control is desirable until return to duty or maximum recovery. From experience in the present clinic this would be possible on a regional basis in Scotland by development of the after-care clinic system under the control of a central traumatic unit. The scheme should include a residential rehabilitation centre.

Treatment entails knowledge of the mental attitude of the disabled as well as of their physical complaints. This is best acquired at present by staff under training in an orthopaedic hospital, where they learn to appreciate many problems of the disabled during convalescence and where the advantages of vocational training are seen.

In an industrial clinic it is desirable that the staff visit the various industries in their region so that they may appreciate fully the working posture of the patient and may be able also to suggest possible graduated light duties in the patient's trade.

The clinic should be under the direction of an orthopaedic surgeon whose case records are strictly confidential and who should refrain from issuing medical reports, on patients under his care, for purposes of litigation.

A liaison officer who has had training as a hospital almoner is indispensable in work of this kind. The social aspects of this problem are not sufficiently appreciated, and extension of social service will do much to solve many of the problems existing between workman and employer.

Anomalies in the Compensation Act are well known to all, and the cases here recorded demonstrate some unusual occurrences and suggest obvious and easily effected improvements for these. Many other aspects of this particular problem are beyond the scope of discussion in this paper.

Trauma and arthritis are inseparable in many patients from the coal-mining industry. Some method of periodic medical supervision of the employees would be an advantage, so that with advancing years and decrease of physical power the miner could be recommended for less arduous duties. It might be possible to adjust wages by introducing a contributory pension scheme.

The mining industry has only limited scope for employing those patients left with residual disability, and it is desirable that regional rehabilitation and training schemes be established for co-operation between heavy and light industries. The recently introduced Government Training Scheme promises a solution to this problem, but it requires to make some more definite arrangements for the patient who is still in receipt of compensation because of residual disability.

FIRST-AID PROPHYLACTIC TREATMENT OF THE COMPRESSION SYNDROME ("CRUSH SYNDROME")

BY

DAVID H. PATEY, M.S.Lond., F.R.C.S.
Surgeon with charge of Out-patients at the Middlesex Hospital; Surgeon, E.M.S.

AND

J. DOUGLAS ROBERTSON, M.D., D.Sc., D.P.H.
Clinical Chemical Pathologist to the Middlesex Hospital

(From the Wards and the Courtauld Institute, Middlesex Hospital)

The destruction of civilian property by air raids has been responsible for the recognition of a new clinical syndrome with characteristic features and often running a typical and fatal course. There is a history that the patient was in a building which collapsed after a bomb hit, and that a limb was pinned down by a beam or heavy object for several hours before release. Immediately on rescue the victim may look surprisingly well despite burial under debris for many hours. But some hours later the patient becomes gravely ill from shock, and, if this phase is successfully overcome, within 24 hours or so fresh anxiety arises owing to haematuria and a low urinary output. Despite measures directed towards stimulating diuresis, the oliguria becomes progressively more marked, terminating in anuria and death from uraemia. The limb that had been pinned down becomes very swollen and hard with oedema soon after its release from the pressure, and is partly or completely paralysed from nerve compression.

Aetiology: A New Conception

This syndrome has been referred to as the "crush syndrome," perhaps incorrectly; for crushing and pulping of the tissues is not a striking feature. On the contrary, it is much more typical for the limb to show no evidence of damage except for some skin abrasions at the site of the compression. A more accurate descriptive term would be "compression syndrome." The cause of this syndrome has given rise to much speculation, and most theories incline to the view that it is the result of a toxin produced in or by damaged tissue. Treatment based on this hypothesis, however, has been very disappointing, and most surgeons in charge of such cases have had the distressing experience of seeing their patients pass from a good general condition to death from anuria despite heroic measures to re-establish the urinary flow. After similar experiences, in March, 1941, we considered that the toxic theory and the treatment based on it were wrong. Instead of the toxic theory based on the release of toxic metabolites from damaged muscles, we thought the compression syndrome might be simply due to a loss of blood constituents from the circulation into the tissues of the limb, the capillaries of which had temporarily lost their function through the long compression. Certain findings seemed to support this conception, including a depletion of the plasma proteins and a very marked swelling of the limb. Indeed, the swelling of the limbs in the fatal cases was so pronounced that small abrasions in the skin were weeping plasma copiously. It became obvious that fluids given intravenously drained into a toneless flaccid limb, the fluid capacity of which must be enormous.

Treatment by Positive Pressure

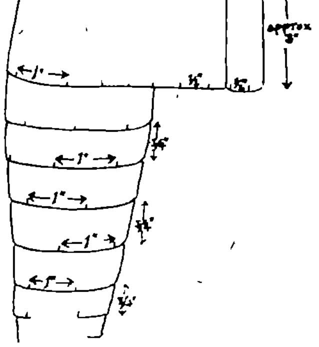
While we were unable to give a complete explanation of the renal phase of the syndrome, we decided to introduce a new form of treatment based on this new conception of the problem. The treatment aimed at restoring extravasated fluid back from the oedematous limb into the circulation. The particular method we used was intermittent positive pressure up to 60 mm. Hg applied through a specially made large blood-pressure cuff firmly bandaged to the limb and connected with a pavaex motor. In June, 1941, we published reports of two cases successfully treated on these lines.

Since this publication we have had no opportunity of treating additional cases. Strong experimental support for our view, however, appeared in a recent paper by Duncan and Blalock (1942). Employing dogs, they have produced a condition similar to the compression syndrome of man. These authors found that if the affected limbs were immediately placed in a pneumatic cuff with a pressure of 40 mm. Hg approximately 75% of the animals recovered, whereas in the control series the recovery rate was only approximately 5%. We (Patey and Robertson, 1942) have recently drawn attention to the confirmatory work of Duncan and Blalock and suggested that routine treatment on the principle we originally recommended is now justified.

Application of the Method

The object of the present communication is to consider the application of the principles outlined by us to first-aid treatment. On our views there would seem to be a justifiable hope that if a simple standard form of first-aid treatment were adopted as soon as a limb had been released from compression many cases of the syndrome would be prevented. But the mere advice to "apply a firm bandage" is not enough. We have studied the question by bandaging on top of a blood-pressure cuff applied to a limb, and noting the increase of pressure produced. With different types of bandage applied in different ways, a wide variety of pressure readings were obtained, varying from ineffective pressure to dangerous pressure occluding the arterial circulation. The factors concerned in pressure produced by bandaging are, first, the force with which the bandage is applied; secondly, the elastic force of the bandage and the degree to which this is stretched; and, thirdly, the number of turns to any given length of limb. We started from the basis that on the facts at present available the pressure to be aimed at was somewhere between 40 mm. Hg (used in dogs by Duncan and Blalock) and 60 mm. Hg (used by us). After this we rejected a number of types of bandage as unsatisfactory—the domette because of its lack of elasticity; the crêpe because of its tendency to stretch and lose its elasticity; and rubber bandages because of the danger of too great pressure and occlusion of arterial supply. We also thought an adhesive bandage undesirable as not allowing for adjustment and reapplication.

Finally we decided on an elastic web bandage made to the pattern of Dickson Wright (by Messrs. Down Bros.), the width of which is a fraction under 3 in. This is a strong bandage of standard strength and elasticity; the latter of which is not easily lost. If this bandage is applied from below upwards stretched to double its unstretched length, with each turn partially covering the previous turn so that 3/4 in. of the lower edge of the latter projects below the fresh turn (see Fig.), an approximate pressure of 40 to 60 mm. Hg is obtained. One or two small practical hints may be given. The bandage should be applied direct to the limb without the intervention of clothing, which will interfere with the effective pressure. The degree of stretch can easily be assessed if the bandage is marked along its lower edge at 1/2-in. intervals. Most people can easily judge 1 in., the distance to which the marks have to be stretched: as a simple check, a halfpenny coin is 1 in. in diameter. Care should be taken to see that the stretch is equal all round; there is a tendency to stretch the bandage to the correct distance in front but not to stretch it sufficiently at the back and sides. We have found that this error is best avoided by applying the bandage in short segments at a time rather than in long loops. The 3/4-in margin can



be assessed by noting some convenient longitudinal line on the bandage. Only a light force with the forearm is required to stretch the bandage to the correct degree, and it should be possible with a little practice for even the inexperienced in bandaging to apply it correctly. In order to avoid oedema below the lower limit of the bandage, the foot and hand should be included. We have found that 2 or 3 bandages are required to cover completely the lower limb, and 1 or 2 for the upper limb.

The question next arises of the further treatment of the case after admission to hospital. If the bandage has been immediately and correctly applied no further local treatment should be required. How long the bandage should stay on will have to be determined by experience. But at present it would seem that it should remain at any rate for some days, and possibly then be reapplied at slightly less pressure. Finally, there is the question of the treatment of the case admitted to hospital with an established oedematous limb either because prophylactic first-aid bandaging has not been used or has been used inefficiently. As already noted, we employed in our two original cases intermittent rather than continuous positive pressure, because we thought on theoretical grounds that the pump-like action of intermittent pressure would be more efficient than continuous pressure, particularly in a paralysed or semi-paralysed limb, in getting rid of established oedema. If this view is confirmed, some other motive force than a pavaex motor will have to be devised before our technique can be generally adopted, owing to the limited number of those machines available. We are investigating the possibility of developing a simple water-pump which fulfils the same purpose.

Summary

The compression syndrome ("crush syndrome") is due to loss of blood constituents into the affected limb.

The principle of treatment should be by positive pressure, to prevent oedema and get rid of any already existing fluid.

The elastic web bandage applied in the way we have described is the simplest efficient means of exerting this positive pressure in a standard manner as a first-aid measure.

First-aid parties should be equipped with these bandages and taught the proper technique of their application. The importance of applying the bandage immediately the limb has been released from compression should be stressed.

The social welfare policy in Sweden is being continued despite the present strain, and the new Swedish State Institute for Public Health in Stockholm was inaugurated by the King last year. The institute is organized in three departments: one for general hygiene, one for occupational hygiene, and a third for the scientific control of foodstuffs. In addition to their intelligence service all three branches carry on scientific research. The first-mentioned department provides education in social hygiene for public health officers, including maternal and child welfare, housing hygiene, tuberculosis care, water, and drainage. The task of the department for occupational hygiene is to investigate and prevent ill-health and accidents arising from unsuitable working conditions. In the sphere of food the prime task of the institute is to prevent the manufacture and sale of products dangerous to health and to assess the value of various foodstuffs from the standpoint of nourishment. Special attention is devoted to investigation and control of vitamins in foodstuffs, fodder, and medicinal preparations. The new institution has at its disposal over 100 laboratories, as well as an animal house, which is said to be the largest in Europe. It employs a staff of about forty persons, not including the medical students studying there, and its head is the well-known Swedish physiologist, Prof. Ernst Abramson. The institute, which is situated within the big "medical city" built in the last few years on the northern outskirts of Stockholm, has cost over £118,000. Part of this has been defrayed by the Rockefeller Foundation.

VAGINISMUS: ITS MANAGEMENT AND PSYCHOGENESIS

BY

JOAN MALLESON, M.B., B.S.

The number of marriages which are legally annulled must be very small compared with the number which are not in fact actually consummated. It is by no means uncommon for women who have been married many years to seek advice on account of dyspareunia, conjugal dissatisfaction, or sterility, and for examination to reveal a hymen partially or totally intact. A large proportion of such patients are genuinely astonished when this fact is made known to them. It would be difficult to assess whether such cases are due more frequently to failure on the part of the husband or that of the wife; because, although one partner may be initially responsible for the difficulty, more often than not this trouble is, so to speak, emotionally "infectious," or, at any rate, accentuated by the other partner being under-competent, over-anxious, or too forbearing. This article will deal with those cases in which the trouble comes mainly from the woman's side, on account of coitus being rendered impossible by spasm of the introital vaginal muscles.

Clinically, the term "vaginismus" denotes a condition of vaginal spasm varying from a constriction at the beginning of coitus (so slight that it may merely discomfort the woman herself) up to the extreme case in which the spasm causes acute pain to the woman and entirely prohibits any penetration by the husband: indeed, the introitus may be so constricted that even the tip of the examining finger can gain no entrance. The spasm may affect the perineal muscles exclusively or may be felt as a varying constriction of the levator ani right up to the vaginal fornices. Accompanying this spasm there is usually a definite adduction of the thighs, even up to the point of cramp-like spasm of the adductor muscles, and invariably the lumbar spine is extended in the position of lordosis. In severe cases the posture adopted is one almost of opisthotonos. A concomitant of the syndrome is a greater or lesser degree of hysterical hyperaesthesia. Rarely, this may be absent, but in some cases it may be more prominent than the spasm itself. The hyperaesthesia is usually of the "glove and stocking" variety, starting exactly at the vaginal introitus, but in extreme cases it may be registered all over the vulva and even over adjacent parts of the abdomen and thighs. Vaginismus need have no relation to an unstretched hymen, and can occur with equal severity in the woman who has borne children as in the virgin. It is known to appear as a secondary protection to some physical lesion (such as urethral caruncle, salpingitis, etc.) which would otherwise cause dyspareunia, but such cases are rare compared with the "idiopathic" vaginismus, and will not be dealt with here.

It is important to realize that a true vaginal spasm cannot be voluntarily produced—that is, it cannot be consciously employed by a woman to evade coitus—and it may appear in spite of the utmost *conscious* willingness to accept the coital act. Fortunately, as will be discussed later, it can very largely be modified by conscious control.

The entire syndrome must, of course, be accepted as psychogenic. Often these women display additional neurotic symptoms, and after marriage many of them develop symptoms of anxiety neurosis, typically precipitated by sexual frustration, although in this case the frustration is self-inflicted. Hence, certain of these cases have of recent years found their way to treatment by psychotherapy or psycho-analysis. Experts in this work assert that the aetiology of the condition appears to be varied, because—as with so many neurotic symptoms—there is a tendency to "over-determine" the original fear against vaginal acceptance.

Observation of a series of cases has suggested a possible common factor which has not yet received recognition. Before outlining this it will be convenient to comment upon the clinical management of these cases, since certain points here may elucidate the hypothesis itself.

Treatment by Persuasion

There can be few medical conditions more gratifying to treat than the case of vaginismus: the average case, even if it has been of long standing, will often resolve after one interview leisurely enough to permit examination and "suggestion." Cases here studied have been drawn from private practice and from the various departments (i.e., gynaecological, sterility, contraceptive) of the North Kensington Women's Welfare Centre. Interviewing in the latter conditions necessitates finding a technique of minimum length compatible with a sufficiently good contact to make treatment by persuasion a feasible proposition.

A proportion of these patients exhibit hostility from the very start; they break the initial appointment or arrive late, and their defensive attitude is often aggressive. While taking a history of dyspareunia it is wisest to accept the patient's own account of the marital situation, but by inquiries to make some assessment as to the normality of either partner's behaviour. When the patient refers to "her fault" or "his fault" it is useful to remind her that "we are not dealing with *faults*, only with temporary difficulties." If the history given suggests that the woman is virginal, before she is asked to undress it is helpful to mention that clearly there may be an unusually difficult "maidenhead" to account for the trouble, or else she may merely have developed the habit of "flinching" and thus be herself causing the discomfort and pain. This idea is new to most women, and they may advantageously consider it while they are preparing for examination.

It is wise to expect difficulty from the patient, and exceptional prudery. If in cases where no physical lesion need be expected a covering blanket is arranged the woman may often be subjected to no visual exposure at all. It is absolutely essential that examination be made in the dorsal position: the alternative position on the side allows of so much lumbar flexion and consequent relaxation that the severity of the introital spasm may be quite concealed. Many mild cases of spasm are probably overlooked in this way. It is helpful to arrange a wall or some other object on the left side of the couch so that the woman can be asked to bend her left knee and keep it resting against the wall. This is invariably easier for her than a direct request to separate the legs, which will certainly revive many painful associations. The case of true vaginismus will at once exhibit lordosis, the axis of the vaginal entrance pointing towards the floor. As the examining finger—well lubricated—reaches the vulva, the left knee is usually brought inwards, still further increasing the inaccessibility of the introitus. At this stage it is advisable to cease examination entirely, and to say, "I am afraid it will be impossible for me to help you if you will not adopt a more helpful position."

Every woman with vaginismus tries, unconsciously, to put the blame or responsibility on to the other person: she expects to be exhorted and physically "attacked." There is no quicker way of modifying these impressions than a kindly but firm refusal to show further interest. Throughout any such interview the most successful contact will be made by an impartial aloofness. Hostility should be met by a firm refusal to be drawn in, and a detached civility will often bring quicker co-operation than a warm eagerness to help.

Many of these women are truly unaware that they render coitus or examination impossible by the thigh adduction, the position being quite unconsciously adopted. An explanation of this is the next stage in examination; and the placing of a folded towel (about 2 in. thick) below the sacrum will demonstrate the required attitude of pelvic flexion. The next attempt must be guided by the woman's reactions: if exceptional hyperaesthesia is present it may be unwise at this interview even to reach the genitalia at all. The woman should be told that this is a fictitious nervous "over-sensitiveness," and she must reflect upon this before she again comes for examination. The very refusal to force her will probably be followed by a request to try once more. The more average patient will allow the insertion of at least one finger, which should be lubricated and should yield entirely to the contour of the contracting passage; pressure against the perineum itself should be avoided. Probably adduction and lordosis will again begin. The patient's attention should be drawn to this, and as she controls her posture she should be told to draw the pelvis up. As the abdominal muscles contract, the levator ani will relax and the spasm and coincident pain will vanish. Given a few minutes' patience, two, or generally three, fingers can be inserted, and the woman realizes for the first time that the vagina is painless and of adequate dimensions. At this stage she should be reminded that her pain has been entirely self-inflicted through her own "flinching," and that her future marital success will therefore depend upon her own efforts. Admittedly, she may be unable to control the vaginal spasm, but if she will attend to flexion of her knees and pelvis, the rest will follow very rapidly.

Most women express themselves astonished that there has been nothing amiss, and are generally glad to have some further talk and explanation. The patient should be made thoroughly to understand that the pain will occur only if the vaginal entrance is "flinching"; and that any hyperaesthesia present must be considered as her own mistranslation of pleasure into pain. Such ideas may appear slightly philosophical, but even uneducated women are often quick to grasp them

Some Practical Measures

Before dismissal the patient should be given a non-greasy lubricant such as K.Y. jelly (or the odourless non-spermicidal Prentif jelly) for lubricating the vaginal entrance, and reminded to place a small support below the buttocks before sexual intercourse. It is unwise at this stage to agree to her using a contraceptive device. If such measures are essential, the husband should employ a condom until the woman is confident and easy about her vaginal functions. Before this stage the use of any appliance seems always to revive the vaginismus. Difficulties are sometimes presented when the husband is incompetent with a condom, and such situations must be met by individual advice. Finally, the woman should be asked to accept sexual relations regularly and to return within a month.

In only the minority of cases will the presence of an unstretchable hymen be found. It is true that efforts to penetrate a difficult hymen may eventually result in psychical distress and some spasm, but this is different in many respects from the "idiopathic" vaginismus that has been described.

Cases in which the hymen is also causing trouble should be treated according to the preference of the medical attendant. It seems usually best to show the woman how to dilate the hymen herself; but if surgical measures seem preferable they should be done under general anaesthesia, and not entail subsequent application of dilators *by anyone except the patient herself.*

The measures above outlined are generally sufficient to ensure complete conjugal penetration. Some women will report absolutely painless acceptance for a few occasions, with later occasional return of spasm; further persuasion may then be required. Each case will, however, display its individual features. Many of these women have other sexual difficulties. Only too often by the time advice is sought either or both partners may be showing signs of anxiety neurosis, increasing sexual coldness, and depression; and often the husband has developed a secondary impotence, which complicates the picture still more. Certain cases, particularly those with hyperaesthesia, show in addition to their "flinching" an extreme distaste for the sexual relationship. Although such cases may by persuasion be encouraged to accept penetration, it is clearly desirable that their attitude should, where possible, be re-orientated by expert psychotherapy as well.

There can be few neurotic symptoms more quickly accessible to cure than the average case of vaginismus. The ideal interview should be of one hour's duration, but often half that time is sufficient. Two somewhat dramatic examples can be chosen to show how quickly resolution may occur even when the complaint has been of very long duration.

Mrs A., a clinic patient, married for 11 years, sought advice on account of sterility. Examination revealed a thin almost intact hymen and typical vaginismus. Three months after her only interview she wrote that sexual relations were improving and a pregnancy was established. This interview could not have exceeded the maximum clinic appointment of thirty minutes. Mrs. B., a scientist aged 36, came to ask about artificial insemination, since sexual relations "were impossible for her." Her first marriage had been annulled after 11 years, and although a doctor had subsequently stretched the hymen, penetration was no easier in her second marriage, which had lasted 4 years and was otherwise very happy. This woman appeared to have little sexual inhibition or strain; but in spite of her doctor's reassurance she still secretly believed that she "must be deformed." Examination showed no hyperaesthesia whatever, but the presence of a strong introital spasm. This relaxed fully to admit three fingers, and the patient subsequently reported easy and immediate establishment of coital relations, with rapidly increasing vaginal feeling. Pregnancy shortly became established.

Before leaving the management of vaginismus, mention should be made of its surgical treatment, whereby the vaginal entrance is relaxed by cutting the posterior muscle fibres of the introitus and vaginal walls. The success of this operation is said to vary greatly; remarkably good results have been claimed, but it is doubtful if the woman with hyperaesthesia or strong sexual prejudice is likely to gain benefit, and it is probably these cases which are therapeutically disappointing.

Aetiology

Let us now give consideration to the causes of this curious disorder. It seems clear that the mechanism is a defensive one: the vagina contracts before it is touched, much as the eyelids blink in anticipation of corneal contact. But why should a small minority of women demonstrate this predetermined and acutely developed anticipation of pain?

In most cases of established vaginismus the woman will mention a previous dread of child-bearing or of sexual pain, or perhaps a preconceived idea that they were "very small inside." Yet such ideas are so common among normal women who show no signs of vaginismus that their description here may be more in the nature of a "rationalization" for the disorder than the actual causative agent. Furthermore, many unmarried women have heard highly exaggerated reports concerning the pain of defloration, yet vaginismus does not as a rule occur among these cases.

Now it has been noticed while interrogating these patients that a common historical factor is often present which does not appear to have received recognition. Many of them have during infancy been "conditioned" to expect pain in the pelvic region by the insertion of a foreign body, the offending object being usually the enema, the suppository, or the old-fashioned soapstick so much employed in Victorian nurseries for the treatment of constipation. Anyone who has witnessed such a procedure will recognize the extreme pain to which the child is subjected. Soap is painful in the rectum as in the eye, and as the infant screams and flings itself into opisthotonos the rectum is instantaneously emptied. The baby who is repeatedly treated in this way will scream and stiffen at the very sight of the attacking object. Here, surely, we have a "conditioning" at the age which is most susceptible to permanent impression.

At first sight it may appear improbable that experience of rectal pain should lead to anticipation of vaginal suffering. To understand such a possibility it is necessary to recapitulate facts of great importance in medical psychology. The rectal, vaginal, and urethral orifices are developed from the original cloaca and possess the same innervation. In very young children the sensations arising in these organs are largely undifferentiated; hence the difficulty in learning sphincteric control and the fact that any of these organs may—and normally to some extent do—receive erotic stimulation during stretching or friction. Thus when a young child experiences pain in either rectum or vagina the resulting impression of the attack will be very similar whichever of the cloacal organs actually received the stimulation.

It is not difficult, therefore, to realize how the child who has come to dread the forcible introduction of a rectal object would respond with fear and shrinking, first in childhood to the vague instinctive ideas of coitus, and then in later life to the actuality of sexual penetration. In some women such trains of feeling must be relegated entirely into the unconscious regions of memory, but in others they are very much part of conscious impression. So large a proportion of women who suffer from vaginismus are able to recall memories of this nature that it is tempting to assume a common pelvic trauma as a basis for all such cases. If this were so the fact should receive recognition, if only for prophylactic purposes.

The possibility of such an association was first suggested by the chance remark of a woman who had suffered from extreme spasm. At her first relaxation of the vagina she stated that the examining finger "Felt exactly like an enema"; and, later, another patient anticipated interrogation by a similar comment, "It feels rather like the bowel."

Since then it has been noticed how many of these patients speak with bitterness of their childhood experiences with enemata. Unfortunately, detailed statistics of these histories have not been kept, but records are available for the rather small figure of 20 consecutive cases of severe vaginismus among educated women. In reply to the question whether they remembered such episodes in childhood, 11 of them replied in the affirmative. Among these answers the following comments were annotated: "Agonizing enemas"; "How I hated them"; "Agonizing soapsticks—at 3½"; "I hated suppositories"; "Mother was always giving us them"; "I loathed them"; "My mother was very heavy-handed"; "I hated them." One patient actually volunteered the illuminating remark, "It was because of enemas I had quite decided I would never marry." It would be interesting to have the replies of a control group of women who recollect such treatments yet have not developed vaginismus, but such have not been collected.

The negative reply of the other 9 does not, of course, exclude the experience, but excludes the probability of the practice being habitual or occurring later than the age of 5 or 6. In fact, psychologists assert that the earlier in infancy a trauma is experienced the more indelible will be its impression. One of these patients agreed to ask her mother for relevant facts, and brought back the surprising reply that no such treatment could have occurred except for soapsticks which, much to the mother's distress, the midwife had insisted on using daily during the first six weeks of life. During examination of these 9 other women 2 exhibited the excessively hostile behaviour so common to such cases: one gave a history of painful catheterization in early childhood, and another of "some painful treatment for soreness."

Neurotic Cases

Although vaginismus is a hysterical symptom, this group of women do not seem to exhibit an unduly high proportion of neurosis. Their sexual behaviour, once the spasm is quiescent, seems fairly representative, vaginal feeling being obtainable in at least half the cases, and none of this series is entirely anaesthetic. Yet it seems certain that the symptom of vaginismus is sometimes "woven in" to an intricate system of neurosis. It might be said that the symptom is *utilized* for other than its original protective purpose. Other trends of feeling such as dread of the penis, hostility to men, parental fixations, etc., may all over-determine the original symptom and make use of it, in their various ways, at unexpected occasions. Herein may lie the explanation for those rare cases of vaginismus in which the symptom develops spontaneously after sexual life has already been established, and for cases which are sometimes amenable to persuasion yet liable to be recurrent. Two long-standing cases may throw light on this phenomenon. Both occur in severely neurotic women who have required psycho-analytic help; neither is included in the above series.

Miss C., aged 28 when first seen, had unsuccessfully attempted intercourse with several men. She had a severe anxiety neurosis and many hypochondriacal symptoms. Although this patient has made an excellent general recovery the symptom is still—after marriage and normal childbirth—apt to recur. She reports that in analysis memories were revived of soapsticks administered by her mother. She considers the vaginismus to be an expression of various conflicting emotions. Mrs. D., aged 26 when first seen, was having her first marriage annulled and still suffers from occasional vaginismus. Sometimes it is quiescent, but may recur suddenly, so that she is never without the risk of its revival. She reports that psycho-analytic investigation has shown various precipitating factors for the vaginal spasm, such as resentment that she is not in an emotional position to become pregnant, or fear that the man is "taking too much from her." At the age of 18 months she had severe dysentery, but we have no proof of any rectal treatment. This patient has no conscious memory of rectal trauma, yet an unconscious one is suggested by her showing great indignation concerning a pre-operative enema, and by the fact that at 17 years she was rectally examined by a woman specialist and suddenly fainted.

Such histories may perhaps be taken as direct support of the theory that vaginismus is caused by early trauma—and further indirect evidence may be deduced by the method of resolution of the disorder.

Conclusion

The technique above described for managing these cases came to be adopted many years before this theory was considered, yet its details seem very rational if the contention is correct. If we assume that each attempt at coitus or examination revives the infantile emotional trauma we have the perfect explanation for the hostile patient—rigid, with dilated pupils. So also is explained her surprise and relief when the examination is not insisted upon. However much originally the patient had protested, the attacking enema was rigidly completed. Here, for the first time, she is neither pleaded with nor overwhelmed. Rather she is left herself in control of the situation, and with the responsibility for refusal—and its consequent results—upon her own shoulders. This may well account for the sudden alteration of attitude so often shown. As it becomes evident to the patient that her (" transferred ") fear and hostility are irrelevant, so the atmosphere of the scene alters. Giving her permission to refuse is often followed by exaggerated gratitude, which undoubtedly is propitious for co-operation and persuasion.

Here, too, may be the explanation of the fact that vaginismus treated by bougies and instruments seems usually to give unsatisfactory results: those patients who endure the treatment, while recognizing that they are no longer " too small," seem often to have had their difficulties even further increased. If this theory is correct such a result would clearly be expected, so that any such treatment should invariably be left in the patient's own hands and should not be relegated to the nurse in charge.

Since the original traumata would have been administered by women, it is possible that the sex of the medical attendant influences the degree of emotion transferred. Perhaps the handling of such cases is best managed in different ways by the male attendant. Certainly the patient's behaviour to medical examination and to coitus do not necessarily run parallel, some cases yielding best to one condition and others showing the opposite reaction. One might suppose that relaxation is best achieved when the emotional atmosphere differs as far as possible from the original one; so that the attendant, even if unfortunately resembling mother or nurse, should at least refrain from behaving like her!

Clearly there is scope for more knowledge about the effects of such early trauma in the male as well: for it is possible that here, too, may be found a basis for some sexual anxiety. If other observers corroborate these findings medical teaching will require to restrain a nursery practice which is by no means uncommon.

A Divisional Hospitals Council for Bristol and district was formed in 1941 and has lately issued its first annual report. The Nuffield Provincial Hospitals Trust authorized a sum of £1,000 to enable grants to be made by the Council in respect of hospital and ancillary medical services and also contributed £315 towards administrative expenses. A survey of hospitals and ancillary services has been undertaken in the Council's area by the Bristol Hospitals Commission, a body of 9 members, including Sir Farquhar Buzzard, who is chairman of the Medical Advisory Council of the Nuffield Trust. Inquiry was made whether it was desirable for further steps to be taken to promote co-ordination or expansion and as to the best means of financing and administering existing services. The Commission paid a second visit to Bristol this year to investigate the contributory scheme problem as it affected that area. During the year the new Divisional Council has taken steps to encourage the formation of similar councils in Bath, Somerset, and Gloucestershire, and a conference has been held with a view to creating a provincial hospitals council to cover Bristol and the West of England, bringing in the areas just named. The report states that valuable preliminary work has been accomplished in this direction.

RELAPSING FEVER IN ADDIS ABABA

BY

P. ROBINSON

Captain, R.A.M.C.

(From the Menelik Hospital, Addis Ababa)

This report is based on 340 cases observed during the second half of 1941.

The transmitting agent of relapsing fever in Abyssinia is, according to some textbooks (Manson-Bahr, Salvioli), the tick *Ornithodorus moubata.* Kirk, however, did not succeed in transmitting Abyssinian relapsing fever by infecting ticks. The spirochaetes in that country have been identified by Scaffidi as a regional variety of *Spirochaeta obermeieri.*

In the present series the spirochaetes were transmitted by the body louse. This is substantiated as follows: (1) mixed infections of relapsing fever and louse-borne typhus are common; (2) spirochaetes are often found in crushed lice collected from relapsing-fever patients; (3) ticks were not found, nor was there a single case in which the " tache noir " (the primary tick-bite sore) was observed.

Diagnosis

The tick film taken as a routine reveals the spirochaetes in most cases of relapsing fever, often also in the afebrile stage. Jaundice is very frequent. The enlarged spleen is as a rule tender. The rash is not easily seen on the dark skin of the Ethiopian, but is more visible than the rash of typhus or typhoid. It consists of small violet-red petechiae, the size of " rose spots," slightly raised, and not fading on pressure. The typical distribution is on the shoulders. Epistaxis is a very useful symptom. Bloody sputum or urine, and diarrhoea with blood, are often mentioned by patients but seldom observed in the hospital. Spirochaetes are sometimes found in the sputum. Pain in the left shoulder is quite common. Pain in the calves, common in other parts of the world, is rare in Abyssinia. The condition of the tongue has been found typical and helpful in the diagnosis of relapsing fever. Four stages may be distinguished. In the first stage, during the first 4 or 5 days of the disease, the tongue is stained brown as in not very severe cases of typhus. In the second stage, covering another week, the tongue is moist and clean. In the third stage the tongue is atrophic, and resembles very much the condition in pernicious anaemia. The fourth stage, not seen more than ten times, but which may occur more often, shows ulcers, single or multiple. The ulcers heal in a week or two without any treatment. Pain in the tongue is common in all stages. The blue tongue seems to be of no diagnostic significance. Systolic and diastolic murmurs are very frequent. In contrast with the murmurs occurring in other infectious diseases their frequency is striking. This and the presence of heart failure in Abyssinia, where rheumatic fever appears to be rare, leads to the assumption that relapsing fever may be one of the chief causes of cardiac lesions there. (Endocarditis of the valves has often been found at necropsy together with other pathological changes typical in relapsing fever.

We found that serum of relapsing-fever patients agglutinates the Kingsbury strain of *Proteus* in a high titre, sometimes up to 1 in 3,200. A history of high pyrexia and chill, and positive XK agglutination with no spirochaetes in the blood, usually indicates a case of relapsing fever. If there is a second rise of temperature the spirochaetes are always found. Mariani, D'Ignazio, Barelli, and Pistoni have described a rare condition which they consider to be a benign typhus showing agglutination with XK up to 1 in 100. The cases they quote are by no means convincing, and we think there is no evidence as to the existence of a typhus-like disease with positive XK in Addis Ababa. Typhus-like diseases with a positive XK have been observed twice in this material; but the titre in both cases dropped considerably, while the X 19 rose steadily and reached its peak in the period that is usual in typhus cases. We consider, therefore, that the XK agglutination in these cases was due to relapsing fever, from which the patients had suffered previously.

The following table shows the diagnostic points in relapsing fever and the frequency of their occurrence. (Some of these points are really complications, but their early appearance renders them symptomatic.)

Spirochaetes in febrile period	100%
,, in afebrile period	38%
Jaundice	72%
Rash	8%
Epistaxis	12%
Tongue symptoms	68%
Enlarged spleen	89%
Tender spleen	44%
Heart murmurs	38%
XK agglutination (done in 168 cases)	98%
Pain in left shoulder	4%

Complications

There is little to say about the course of the illness as all these cases were treated immediately and responded admirably to N.A.B. In about 6% malaria was found simultaneously, and the quinine treatment did not interfere with the N.A.B. (Our experience with typhus allows us to assume that the relapsing-fever infection provokes the malaria relapse.) Typhus in about 10% of the cases took its normal course. Jaundice (72%) was the most frequent complication, and formed no contraindication to the specific treatment. The next most frequent, and the severest, were haemorrhages from the mucous membranes (12%): if untreated the patients lose litres of blood. Occasionally bleeding in the central nervous system occurs, causing paralysis. Only three such cases have been observed; one of these patients died. Other complications are rare: oedema (6 cases), acute thyroiditis (3), parotitis (8), perisplenitis (4), infarcts in the spleen (2—both fatal). Spleen infarcts, however, are not always fatal, as we have found them occasionally in necropsies after death due to other causes. The last complication is pachymeningitis (3 cases—all fatal). In 2 of these 3 cases spirochaetes were found in the C.S.F. Examination of the C.S.F. in uncomplicated cases of relapsing fever revealed normal conditions. Dutton's spirochaetes have been found by Lodewyckx in the C.S.F. in 3 cases. In others a hyperlymphocytosis was noted.

Relapses occur in spite of treatment. In 16% of the cases there was one relapse and in 4% there were two relapses. The longest interval observed was 27 days.

Treatment

One, two, or three injections of N.A.B. are necessary, the first injection being repeated if the temperature does not fall the day after the injection or if there is a fresh rise. Haemorrhages if severe must be treated. After having observed that in some cases the blood did not clot, we started to estimate the "prothrombin time" and found it prolonged in every instance, even if not complicated by haemorrhage. As vitamin K therapy is the method of choice in prothrombin deficiency it was tried, and proved to be the ideal treatment. We used 5 to 10 mg. of 2-methyl-1:4-naphthoquinone in oily solution intramuscularly (1 to 2 ampoules of kapilin-Glaxo). Vitamin K preparations should, we think, be given in all relapsing-fever cases to prevent haemorrhages.

The case mortality was 3.5%. At necropsy, perisplenitis was found in almost every case, and sometimes infarcts in the spleen. Endocarditis was common.

Conclusion and Summary

Relapsing fever in Addis Ababa is transmitted by lice.

Spirochaetes are often found during the afebrile stage.

The rash has a typical appearance—a violet shade; and a typical localization—the shoulders.

Tongue pain, atrophy, and ulcerations are typical of relapsing fever.

Relapsing fever in Addis Ababa is assumed to cause cardiac lesions.

All cases show a positive agglutination with XK.

Haemorrhages from the mucous membranes are due to prothrombin deficiency and can be treated successfully with vitamin K.

Relapses occur in spite of N.A.B. treatment.

The mortality rate was 3.5%.

In cases of pachymeningitis, spirochaetes have been found in the C.S.F.

Perisplenitis, spleen infarcts, and endocarditis have been observed at necropsy.

I wish to thank the D.M.S., East African Forces, for the permission to publish this paper.

MUSTARD-GAS BURNS

BY

JAMES GRANT, M.D., D.P.H.
Medical Officer of Health

AND

T. F. RITCHIE, M.B., Ch.B.
Assistant Medical Officer (Civil Defence), Gateshead County Borough

The following recent experience emphasizes anew certain features of the effects of mustard gas.

On July 1, 1942, a site-decontamination demonstration involving the use of mustard gas was staged elsewhere in this region. Members of the Civil Defence Services of various areas were in attendance. By some mischance premature functioning of the demonstration weapon occurred, resulting in some of the spectators being affected, including 10 persons from this borough.

These patients had been entirely unaware of any contact with liquid mustard gas, which obviously had fallen in the form of fine droplets on their exposed skins. As a matter of fact, part of the bomb casing fell within two yards of the Gateshead party.

Photographs were taken of some of the burns on July 4 and 5, and two of these are reproduced here. The following abbreviated table summarizes each case and the length of the latent period:

Case	Latent Period	Site of Burns	Remarks
1	2½ hours	Left side of neck and temple; outer angle of orbit; left hand	
2	1½ ,,	Left side of neck and angle of jaw; back of left hand; front of right wrist	Faintness, nausea, perspiration on 2/7/42. Burnt by vapour in last war
3	Leg, 2 hours; neck, 8 hours	Left side of neck; right thigh and calf	
4	8 hours	Left side of neck and temple	
5	6 ,,	Bridge of nose; left cheek and face	
6	2½ ,,	Left side of neck; right hand. Small patch ½ in. below left eyelid	Nausea and vomiting on 3/7/42. Blister-gas burn in last war
7	14 ,,	Left side of neck and left hand	Nausea and vomiting, 3/7/42
8	12 ,,	Left side of neck; pinna and lobe of left ear	,, ,,
9	About 12 hours	Left side of neck	
10	,, 50 ,,	,, ,, ,,	

When first seen the lesions took the form in all cases of a sharply defined raised erythema of the skin, and in 7 cases there were also varying degrees of punctate vesication of the burns of the neck. In one of these cases the vesicles continued to appear for a period of approximately 30 hours after exposure. One individual sustained burns on the leg due to the liquid penetrating his clothing. The vesicles were incised where present, and the burnt areas were bathed with weak dettol solution and subsequently anointed with sulphanilamide paste. Four of the patients complained of nausea either one or two days after the onset of the lesions, and these symptoms lasted for approximately 12 hours. The incised vesicles took on the form of yellowish-brown crusts which later separated, to leave pale areas in contrast with the erythematous skin, which became a dark coppery colour, so that the skin of the neck in particular had a mottled appearance. No septic complications were met with in the subsequent progress of the lesions. Two of the patients had sustained mustard-gas burns in the last war, and they had the shortest latent periods after exposure. One still complained 12 days afterwards of an intermittent burning sensation in the neck which interfered with his sleep.

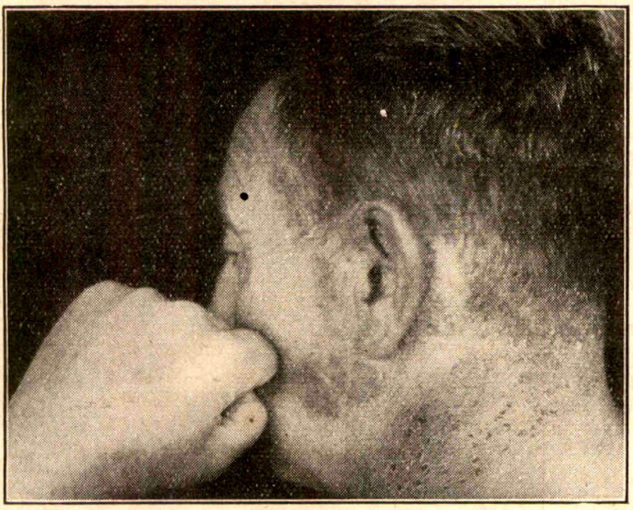

FIG. 1

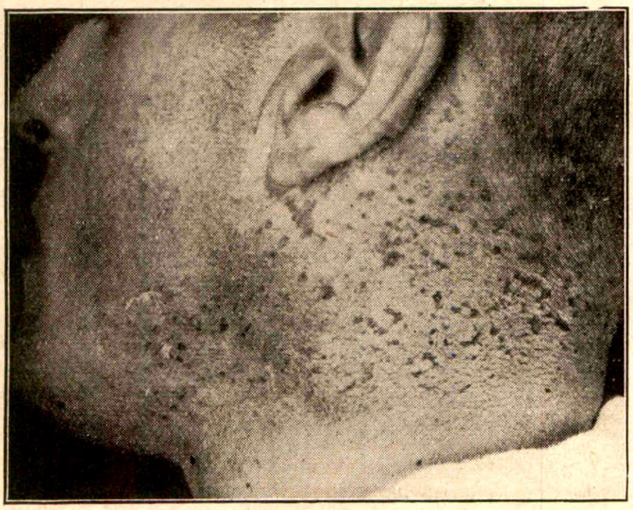

FIG. 2

Discussion

The 10 members of the local authority service present at this demonstration were all highly trained in anti-gas precautions. They were fully aware of the consequence of exposure to mustard gas, but not one realized that he had been splashed by droplets. They all assumed their respirators immediately the accident occurred and considered themselves safe. Conjunctivitis was not evident in any of the cases, probably owing to this; but two of the men had narrow escapes, as they sustained tiny burns on the eyelids.

Sulphanilamide paste apparently countered the danger of skin sepsis and proved a very satisfactory dressing.

Summary

We report 10 cases of mustard-gas burns sustained as the result of an accident during an A.R.P. demonstration.

Attention is directed to the insidious action of mustard gas, a feature that was of course noted in the last war.

The incident described emphasizes the need for strict observance of the recommended safety precautions required in the conduct of such demonstrations.

Medical Memoranda

Fulminating Purpura and Adrenal Haemorrhage

Cases of fulminating purpura and adrenal haemorrhage (Waterhouse-Friderichsen syndrome) are rare enough to be worth recording.

CASE REPORT

At about 12 noon on March 11, 1942, in response to an urgent call, I visited a male child aged 4 months who had suddenly become seriously ill. On my arrival the mother gave the following history: The child had always seemed perfectly healthy. On the previous evening he appeared to be quite normal and had taken his feed as usual. He had slept through the night. On the morning of March 11 he took his feed, though not very readily, the bowels had acted and were normal in appearance, but the mother had noted a rash behind his ears. As the rash began to spread over his face the mother thought that he was "going in" for measles. At about 11.30 a.m. the child suddenly became much worse; his breathing became very rapid and noisy, and as he appeared to be unconscious the mother became very alarmed.

Examination showed a well-nourished, extremely shocked, and cyanosed child, presenting almost a complete Hippocratic facies. A well-marked purpuric rash covered the face profusely, and was also present on the abdomen and on both extremities. There were also large blotches of ecchymoses on both thighs and forearms. The rectal temperature was 101.4°, the pulse about 160, the respirations 64, accompanied by a loud stertor. Nothing abnormal could be seen in the mouth, throat, or nose. The lungs were resonant, the abdomen was flaccid, and rectal examination revealed a soft yellow stool adherent to the gloved finger. There was no head rigidity; Kernig's sign was negative; the pupils were dilated, equal, and did not react to light. No history of a convulsion was elicited. The child died in my presence at 1 p.m.

I was allowed to perform a post-mortem examination on the following day. The heart, lungs, and gastro-intestinal tract presented no abnormality; the mesenteric glands were not enlarged; the liver, kidneys, spleen, and thymus appeared normal. There was, however, haemorrhage into both suprarenal glands, both cortical and medullary portions being involved. No bleeding had occurred into the adjacent tissues. Permission was not granted to examine the brain and spinal cord.

COMMENT
